Contents

List of contributors, ix
Foreword, xv
Preface, xvii

Part I: Conceptual issues and research approaches

A: Developmental psychopathology

- 1** Development and psychopathology: a life course perspective, 5
Barbara Maughan and Stephan Collishaw
- 2** Diagnosis, diagnostic formulations, and classification, 17
Michael Rutter and Daniel S. Pine
- 3** Neurodevelopmental disorders, 31
Anita Thapar and Michael Rutter
- 4** Conceptual issues and empirical challenges in the disruptive behavior disorders, 41
Jonathan Hill and Barbara Maughan
- 5** Emotion, emotion regulation and emotional disorders: conceptual issues for clinicians and neuroscientists, 53
Argyris Stringaris
- 6** Attachment: normal development, individual differences, and associations with experience, 65
Mary Dozier and Kristin Bernard
- 7** Infant/early years mental health, 79
Tuula Tamminen and Kaija Puura
- 8** Temperament: individual differences in reactivity and regulation as antecedent to personality, 93
Nathan A. Fox and Olga L. Walker

B: Neurobiology

- 9** Neurobiological perspectives on developmental psychopathology, 107
Mark H. Johnson
- 10** Systems neuroscience, 119
Daniel S. Pine

- 11** Neuroimaging in child psychiatry, 132
Kevin Pelphrey, Brent Vander Wyk and Michael Crowley

C: Epidemiology, interventions and services

- 12** Using natural experiments and animal models to study causal hypotheses in relation to child mental health problems, 145
Anita Thapar and Michael Rutter
- 13** Using epidemiology to plan, organize, and evaluate services for children and adolescents with mental health problems, 163
Miranda Wolpert and Tamsin Ford
- 14** Evaluating interventions, 177
Helena Chmura Kraemer
- 15** What clinicians need to know about statistical issues and methods, 188
Andrew Pickles and Rachael Bedford
- 16** Global psychiatry, 201
Atif Rahman and Christian Kielsing
- 17** Prevention of mental disorders and promotion of competence, 215
Mark T. Greenberg and Nathaniel R. Riggs
- 18** Health economics, 227
Martin Knapp and Sara Evans-Lacko
- 19** Legal issues in the care and treatment of children with mental health problems, 239
Brenda Hale and Jane Fortin
- 20** Children's testimony: a scientific framework for evaluating the reliability of children's statements, 250
Maggie Bruck and Stephen J. Ceci
- 21** Residential and foster care, 261
Marinus H. van IJzendoorn, Marian J. Bakermans-Kranenburg and Stephen Scott
- 22** Adoption, 273
Nancy J. Cohen and Fataneh Farnia

Part II: Influences on psychopathology

- 23** Biology of environmental effects, 287
Michael Rutter and Camilla Azis-Clauson
- 24** Genetics, 303
Matthew W. State and Anita Thapar
- 25** Epigenetics and the developmental origins of vulnerability for mental disorders, 317
Michael J. Meaney and Kieran J. O'Donnell
- 26** Psychosocial adversity, 330
Jennifer Jenkins, Sheri Madigan and Louise Arseneault
- 27** Resilience: concepts, findings, and clinical implications, 341
Michael Rutter
- 28** Impact of parental psychiatric disorder and physical illness, 352
Alan Stein and Gordon Harold
- 29** Child maltreatment, 364
Andrea Danese and Eamon McCrory
- 30** Child sexual abuse, 376
Danya Glaser
- 31** Brain disorders and psychopathology, 389
Isobel Heyman, David Skuse and Robert Goodman

Part III: Approaching the clinical encounter

A: The clinical assessment

- 32** Clinical assessment and diagnostic formulation, 407
James F. Leckman and Eric Taylor
- 33** Use of structured interviews, rating scales, and observational methods in clinical settings, 419
Prudence W. Fisher, Erica M. Chin and Hilary B. Vidair
- 34** Psychological assessment in the clinical context, 436
Tony Charman, Jane Hood and Patricia Howlin
- 35** Physical examination and medical investigation, 449
Kenneth E. Towbin

B: Considering and selecting available treatments

- 36** Psychological interventions: overview and critical issues for the field, 463
John R. Weisz, Mei Yi Ng and Nancy Lau
- 37** Parenting programs, 483
Stephen Scott and Frances Gardner
- 38** Cognitive-behavioral therapy, behavioral therapy, and related treatments in children, 496
Philip C. Kendall, Jeremy S. Peterman and Colleen M. Cummings

- 39** Family interventions, 510

Ivan Eisler and Judith Lask

- 40** Relationship-based treatments, 521

Jonathan Green

- 41** Educational interventions for children's learning difficulties, 533

Charles Hulme and Monica Melby-Lervåg

- 42** School-based mental health interventions, 545

Sally N. Merry and Stephanie Moor

- 43** Pharmacological, medically-led and related treatments, 559

Eric Taylor

C: Contexts of the clinical encounter and specific clinical situations

- 44** Refugee, asylum-seeking and internally displaced children and adolescents, 575
Mina Fazel, Ruth Reed and Alan Stein
- 45** Pediatric consultation and psychiatric aspects of somatic disease, 586
Elizabeth Pinsky, Paula K. Rauch and Annah N. Abrams
- 46** Mental health and resilience in children and adolescents affected by HIV/AIDS, 599
Theresa S. Betancourt, David J. Grelotti and Nathan B. Hansen
- 47** Children with specific sensory impairments, 612
Naomi Dale and Lindsey Edwards
- 48** Assessment and treatment in nonspecialist community health care settings, 623
Tami Kramer and M. Elena Garralda
- 49** Forensic psychiatry, 636
Susan Young and Richard Church
- 50** Provision of intensive treatment: intensive outreach, day units, and in-patient units, 648
Anthony James and Anne Worrall-Davies

Part IV: Clinical syndromes: neurodevelopmental, emotional, behavioral, somatic/body-brain

A: Neurodevelopmental

- 51** Autism spectrum disorder, 665
Ann Le Couteur and Peter Szatmari
- 52** Disorders of speech, language, and communication, 683
Courtenay Frazier Norbury and Rhea Paul
- 53** Disorders of reading, mathematical and motor development, 702
Margaret J. Snowling and Charles Hulme

54 Intellectual disability, 719
Emily Simonoff

55 ADHD and hyperkinetic disorder, 738
Edmund J.S. Sonuga-Barke and Eric Taylor

56 Tic disorders, 757
James F. Leckman and Michael H. Bloch

57 Schizophrenia and psychosis, 774
Chris Hollis and Lena Palaniyappan

B: Emotional

58 Disorders of attachment and social engagement related to deprivation, 795
Charles H. Zeanah and Anna T. Smyke

59 Post traumatic stress disorder, 806
William Yule and Patrick Smith

60 Anxiety disorders, 822
Daniel S. Pine and Rachel G. Klein

61 Obsessive compulsive disorder, 841
Judith L. Rapoport and Philip Shaw

62 Bipolar disorder in childhood, 858
Ellen Leibenluft and Daniel P. Dickstein

63 Depressive disorders in childhood and adolescence, 874
David Brent and Fadi Maalouf

64 Suicidal behavior and self-harm, 893
Keith Hawton, Rory C. O'Connor and Kate E.A. Saunders

C: Behavioral

65 Oppositional and conduct disorders, 913
Stephen Scott

66 Substance-related and addictive disorders, 931
Thomas J. Crowley and Joseph T. Sakai

67 Disorders of personality, 950
Jonathan Hill

68 Developmental risk for psychopathy, 966
Essi Viding and Eamon McCrory

D: Somatic/body-brain

69 Gender dysphoria and paraphilic sexual disorders, 983
Kenneth J. Zucker and Michael C. Seto

70 Sleep interventions: a developmental perspective, 999
Allison G. Harvey and Eleanor L. McGlinchey

71 Feeding and eating disorders, 1016
Rachel Bryant-Waugh and Beth Watkins

72 Somatoform and related disorders, 1035
M. Elena Garralda and Charlotte Ulrikka Rask

Index, 1055

List of contributors

Annah N. Abrams MD

Chief, Child and Adolescent Psychiatry Consultation Service, Massachusetts General Hospital, Boston, MA, USA

Louise Arseneault PhD

Professor of Developmental Psychology, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UK

Camilla Azis-Clauson BSc

Research Psychologist, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UK

Marian J. Bakermans-Kranenburg PhD

Professor, Center for Child and Family Studies, Leiden University, Leiden, The Netherlands

Rachael Bedford PhD

Sir Henry Wellcome Postdoctoral Fellow, Department of Biostatistics, Institute of Psychiatry, Psychology and Neuroscience, London, UK

Kristin Bernard PhD

Assistant Professor of Clinical Psychology, Department of Psychology, Stony Brook University, Stony Brook, NY, USA

Theresa S. Betancourt ScD, MA

Associate Professor and Director, Department of Global Health and Population, Harvard School of Public Health, Harvard University, Boston, MA, USA

Michael H. Bloch MD

Assistant Professor, Child Study Center and the Department of Psychiatry, Yale University, New Haven, CT, USA

David Brent MD, MS Hyg

Endowed Chair in Suicide Studies and Professor of Psychiatry, Pediatrics, Epidemiology, and Clinical and Translational Science, Western Psychiatric Institute, University of Pittsburgh, Pittsburgh, PA, USA

Maggie Bruck PhD

Professor, School of Medicine, Johns Hopkins University, Baltimore, MD, USA

Rachel Bryant-Waugh BSc, MSc, DPhil

Consultant Clinical Psychologist, Lead for Feeding Disorders Team, Joint Head of Feeding and Eating Disorders Service, Department of Child and Adolescent Mental Health, Great Ormond Street Hospital for Children NHS Foundation Trust, London, UK

Stephen J. Ceci PhD

Helen L. Carr Professor of Developmental Psychology, Department of Human Development, Cornell University, New York, USA

Tony Charman MA, Msc, PhD

Professor of Clinical Child Psychology, Department of Psychology, Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, UK

Erica M. Chin PhD

Assistant Professor, Division of Child and Adolescent Psychiatry, New York Presbyterian Hospital, Columbia University Medical Center, New York, NY, USA

Richard Church MB, BChir, MRCPsych, DCH, AKC

Consultant Psychiatrist, South London and Maudsley NHS Foundation Trust, London, UK

Nancy J. Cohen PhD, CPsych

Professor of Child and Adolescent Psychiatry, Department of Psychiatry, University of Toronto, Toronto, Ontario, Canada
Director of Research, Hincks-Dellcrest Center, Gail Appel Institute, Toronto, Ontario, Canada

Stephan Collishaw DPhil

Senior Lecturer, Institute of Psychological Medicine and Clinical Neurosciences, Cardiff University School of Medicine, Cardiff, UK

Michael Crowley PhD

Assistant Professor, Child Study Center Program for Anxiety Disorders; Associate Director, Developmental Electrophysiology Laboratory, Yale University School of Medicine, New Haven, CT, USA

Thomas J. Crowley MD

Professor, Department of Psychiatry, University of Colorado School of Medicine, Aurora, CO, USA

Colleen M. Cummings PhD

Child, Pediatric and Adolescent Psychologist, Department of Psychology, Temple University, Philadelphia, PA, USA

Naomi Dale MA, PhD, CPsychol

Consultant Clinical Psychologist, Head of Psychology (Neurodisability), The Wolfson Neurodisability Service, Great Ormond Street Hospital, NHS Foundation Trust, London, UK

Andrea Danese MD PhD

Clinical Senior Lecturer and Consultant, Child and Adolescent Psychiatrist, Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, UK
National and Specialist Clinic for Child Traumatic Stress and Anxiety Disorders, South London and Maudsley NHS Foundation Trust, London, UK

Daniel P. Dickstein MD

Director, PediMIND Program, Associate Director of Research, Bradley Hospital, East Providence, RI, USA
Division of Child Psychiatry, Department of Psychiatry and Human Behavior, Alpert Medical School of Brown University, Providence, RI, USA

Mary Dozier

Amy E DuPont Chair of Child Development, Professor, Department of Psychological and Brain Sciences, University of Delaware, Newark, DE, USA

Lindsey Edwards PhD

Consultant Clinical Psychologist, Cochlear Implant Programme, Great Ormond Street Hospital, NHS Foundation Trust, London, UK

Ivan Eisler MA, PhD, FAcSS, FAED

Emeritus Professor of Family Psychology and Family Therapy, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UK

Sara Evans-Lacko PhD

Lecturer, Institute of Psychiatry, Psychology and Neuroscience, King's College London, UK

Fataneh Farnia PhD

Assistant Professor, Department of Psychiatry, University of Toronto, Toronto, Ontario, Canada
Hincks-Dellcrest Centre, Gail Appel Institute, Toronto, Ontario, Canada

Mina Fazel MB BCH, MRCPsych, DM

Research Fellow, Department of Psychiatry, University of Oxford, Oxford, UK

Prudence W. Fisher PhD

Assistant Professor, Division of Child and Adolescent Psychiatry, Columbia University and New York State Psychiatric Institute, New York, NY USA

Tamsin Ford PhD, FRCPsych

Professor of Child and Adolescent Psychiatry, Institute of Health Research, University of Exeter Medical School, Exeter, UK

Jane Fortin LLB, Solicitor

Emeritus Professor, Sussex Law School, University of Sussex, Brighton, UK

Nathan A. Fox PhD

Distinguished University Professor and Interim Chair, Department of Human Development and Quantitative Methodology, University of Maryland, College Park, MD, USA

Frances Gardner MPhil, DPhil

Professor of Child and Family Psychology, Centre for Evidence-Based Intervention, Department of Social Policy and Intervention, University of Oxford, Oxford, UK

M. Elena Garraalda MD, MPhil, FRCPsych, FRCPCH DPM

Emeritus Professor, Academic Unit of Child and Adolescent Psychiatry, Imperial College London, London, UK

Danya Glaser MB, DCH, FRCPsych, Hon FRCPCH

Honorary Consultant Child and Adolescent Psychiatrist, Great Ormond Street Hospital for Children NHS Foundation Trust, London, UK

Robert Goodman PhD FRCPsych

Professor of Brain and Behavioral Medicine, Institute of Psychiatry, Psychology and Neuroscience, King's College London, UK

Jonathan Green MA, MBBS, FRCPsych, DCH

Professor of Child and Adolescent Psychiatry, Institute of Brain, Behavior and Mental Health, University of Manchester and Manchester Academic Health Sciences Centre; Honorable Consultant, Royal Manchester Children's Hospital, Manchester, UK

Mark T. Greenberg PhD

Bennett Chair in Prevention Research Center for the Promotion of Human Development, Pennsylvania State University, University Park, PA, USA

David J. Grelotti MD

Assistant Professor, Department of Psychiatry, University of California San Diego School of Medicine, La Jolla, CA, USA
Staff Psychiatrist, Owen HIV Clinic, University of California San Diego Health System, San Diego, CA, USA

Brenda Hale DBE, PC, MA (Cantab), FRCPsych (Hon), LL.D (Hon), DUniv (Hon), FBA

Deputy President, Supreme Court of the United Kingdom, London, UK

Nathan B. Hansen PhD

Associate Professor and Department Head, Department of Health Promotion and Behavior, College of Public Health, University of Georgia, Athens, GA, USA

Gordon Harold BSc, MSc, PhD

Director and Andrew and Virginia Rudd Chair in Psychology, Rudd Centre for Adoption Research and Practice, School of Psychology, University of Sussex, Brighton, UK

Allison G. Harvey PhD

Professor of Psychology, Department of Psychology, University of California, Berkeley, CA, USA

Keith Hawton FMedSci DSc FRCPsych

Director, Centre for Suicide Research, University Department of Psychiatry, Warneford Hospital, Oxford, UK

Isobel Heyman MBBS PhD FRCPsych

Consultant Child and Adolescent Psychiatrist, Psychological Medicine, Great Ormond Street Hospital for Children, London, UK
Honorary Professor, Institute of Child Health, UCL School of Life and Medical Sciences, University College London, London, UK

Jonathan Hill BA, MBBChir, MRCP, FRCPsych

Professor of Child and Adolescent Psychiatry, School of Psychology and Clinical Language Sciences, University of Reading, Reading, UK

Chris Hollis PhD MRCPsych

Professor of Child and Adolescent Psychiatry, Division of Psychiatry and Applied Psychology, Institute of Mental Health, University of Nottingham, UK

Jane Hood BSc, MSc, PGCE, DEdPsy, C. Psychol

Consultant Pediatric Neuropsychologist and Educational Psychologist, Centre for Developmental Neuropsychology, Oxon, UK

Patricia Howlin BA, MSc, PhD, FBPS

Emeritus Professor of Clinical Child Psychology, Department of Psychology, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UK; Professor of Developmental Disability, Faculty of Health Sciences, University of Sydney, New South Wales, Australia

Charles Hulme MA, DPhil, FBPsS

Professor of Psychology, Division of Psychology and Language Sciences, University College London, London, UK

Marinus H. van IJzendoorn PhD

Professor of Child and Family Studies, Centre for Child and Family Studies, Leiden University, Leiden, The Netherlands

Anthony James MB, BS, MRCP, MRCPsych, MPhil, MA(Oxon)

Consultant Child and Adolescent Psychiatrist, Department of Psychiatry, University of Oxford, Oxford, UK

Jennifer Jenkins PhD

Atkinson Chair of Early Child Development and Education, Applied Psychology and Human Development, University of Toronto, Ontario, Canada

Mark H. Johnson PhD FBA

Director, Centre for Brain and Cognitive Development, School of Psychology, Birkbeck College, University of London, London, UK

Philip C. Kendall PhD, ABPP

Distinguished University Professor and Laura H. Carnell Professor of Psychology, Department of Psychology, Temple University, Philadelphia, PA, USA

Christian Kieling MD, PhD

Lecturer, Department of Psychiatry, School of Medicine, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil

Rachel G. Klein PhD

Fascitelli Family Professor The Child Study Center at New York University Langone Medical Center Department of Child and Adolescent Psychiatry, New York University School of Medicine, NY, USA

Martin Knapp PhD

Professor of Social Policy, Department of Social Policy, London School of Economics and Political Science, London, UK

Helena Chmura Kraemer PhD

Professor of Biostatistics in Psychiatry (Emerita), Stanford University, Stanford, CA, USA
Adjunct, Department of Psychiatry, School of Medicine, University of Pittsburgh, Pittsburgh, USA

Tami Kramer MBBCh, MRCPsych

Consultant Child and Adolescent Psychiatrist, and Senior Clinical Research Fellow, Academic Unit of Child and Adolescent Psychiatry, Imperial College London, London, UK

Judith Lask BA, MSc, ADFT, CQSW

Family and Systemic Psychotherapist, University of Exeter, Exeter, UK

Nancy Lau AM

PhD Candidate in Clinical Psychology, Department of Psychology, Harvard University, Cambridge, MA, USA

Ann Le Couteur BSc Psychology, MBBS, FRC Psych, FRCPCH

Professor of Child and Adolescent Psychiatry, Institute of Health and Society, Newcastle University, Newcastle upon Tyne, UK and Northumberland, Tyne and Wear NHS Foundation Trust, Newcastle upon Tyne, UK

James F. Leckman MD, PhD

Neison Harris Professor, Child Study Center and the Departments of Psychiatry, Pediatrics and Psychology, Yale University, New Haven, CT, USA

Ellen Leibenluft MD

Senior Investigator and Chief of the Section on Bipolar Spectrum Disorders, Emotion and Development Branch, National Institute of Mental Health, Bethesda, MD, USA

Fadi Maalouf MD

Director, Child and Adolescent Psychiatry Program, Department of Psychiatry, American University of Beirut, Beirut, Lebanon

Sheri Madigan PhD

Post Doctoral Fellow, Applied Psychology and Human Development, University of Toronto, Ontario, Canada

Barbara Maughan PhD

Professor of Developmental Epidemiology, MRC Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UK

Eamon McCrory PhD DCLinPsy

Professor of Developmental Neuroscience and Psychopathology Division of Psychology and Language Sciences, University College London, London, UK
Anna Freud Centre, London, UK

Eleanor L. McGlinchey PhD

Postdoctoral research fellow, Department of Psychology, University of California, Berkeley, CA, USA
New York State Psychiatric Institute, Columbia University Medical Center, New York, NY, USA

Michael J. Meaney CM, CQ, FRSC, PhD

James McGill Professor, Ludmer Centre for Neuroinformatics and Mental Health, Douglas Mental Health University Institute, McGill University, Montreal, Canada
Singapore Institute of Clinical Sciences, A*STAR, Brenner Centre for Molecular Medicine, Singapore

Monica Melby-Lervåg PhD

Professor, Deputy Dean for Research, Department of Special Needs Education, University of Oslo, Oslo, Norway

Sally N Merry FRANZCP CCAP

Professor, Department of Psychological Medicine, Auckland School of Medicine, University of Auckland, Auckland, New Zealand

Stephanie Moor MRCPsych

Child and Adolescent Psychiatrist and Senior Lecturer, Department of Psychological Medicine, Christchurch School of Medicine, University of Otago, Christchurch, New Zealand

Mei Yi Ng AM

Ph.D. Candidate in Clinical Psychology, Department of Psychology, Harvard University, Cambridge, MA, USA

Courtenay Frazier Norbury DPhil

Professor, Department of Psychology, Royal Holloway, University of London, Surrey, UK

Rory C. O'Connor PhD, CPsychol, AFBPsS, FAcSS

Professor of Health Psychology, Suicidal Behaviour Research Laboratory, Institute of Health and Wellbeing, University of Glasgow, Glasgow, UK

Kieran J. O'Donnell PhD

Postdoctoral Fellow, Ludmer Centre for Neuroinformatics and Mental Health, Douglas Mental Health University Institute, McGill University, Montreal, Canada

Lena Palaniyappan PhD MRCPsych

Clinical Associate Professor, Division of Psychiatry and Applied Psychology, Institute of Mental Health, University of Nottingham, Nottingham, UK

Rhea Paul Ph, CCC-SLP

Professor and Chair, Department of Speech-Language Pathology, College of Health Professions, Sacred Heart University, Fairfield, CT, USA

Kevin Pelphrey PhD

Harris Professor, Child Study Center and Department of Psychology, Yale University, New Haven, CT, USA

Jeremy S. Peterman MA

PhD Student, Clinical Psychology, Child and Adolescent Anxiety Disorders Clinic (CAADC), Department of Psychology, Temple University, Philadelphia, PA, USA

Andrew Pickles PhD

Chair in Biostatistics, Department of Biostatistics, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UK

Daniel S. Pine MD

Chief, Section on Development and Affective Neuroscience, National Institute of Mental Health (NIMH) Intramural Research Program, Bethesda, MD, USA

Elizabeth Pinsky MD

Clinical Fellow in Psychiatry, Child and Adolescent Psychiatry Consultation Service, Massachusetts General Hospital, Boston, MA, USA

Kaija Puura MD, PhD

Associate Professor, Department of Child Psychiatry, University of Tampere and Tampere University Hospital, Tampere, Finland

Atif Rahman MRCPsych, PhD

Professor of Child Psychiatry, Institute of Psychology, Health and Society, University of Liverpool, Liverpool, UK

Judith L. Rapoport MD

Chief, Section on Childhood Neuropsychiatric Disorders, Child Psychiatry Branch, National Institute of Mental Health, Bethesda, MD, USA

Charlotte Ulrikka Rask MD, PhD

Consultant, Senior Researcher, Research Clinic for Functional Disorders and Psychosomatics, Aarhus University Hospital, Aarhus, Denmark
Clinical Associate Professor, Regional Centre for Child and Adolescent Psychiatry, Aarhus University Hospital, Aarhus, Denmark

Paula K. Rauch MD

Director, Marjorie E. Korff, PACT (Parenting At a Challenging Time) Program, Child and Adolescent Psychiatry Consultation Service and MGH Cancer Center Parenting Program, Massachusetts General Hospital, Boston, MA, USA

Ruth Reed MB BChir, MRCPsych, MRCPCH

Specialty Registrar, Department of Psychiatry, University of Oxford, Oxford, UK

Nathaniel R. Riggs PhD

Associate Professor of Human Development and Family Studies, Department of Human Development and Family Studies, Colorado State University, Fort Collins, CO, USA

Michael Rutter CBE, MD, FRCP, FRCPsych, FRS, FMedSci, FBA

Professor of Developmental Psychopathology, Social, Genetic and Developmental Psychiatry (SGDP) Research Centre, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UK

Joseph T. Sakai MD

Associate Professor, Department of Psychiatry, University of Colorado School of Medicine, Aurora, CO, USA

Kate E.A. Saunders BMBCh, MA, MRCPsych

Honorary Consultant Psychiatrist, Department of Psychiatry, University of Oxford, Oxford, UK

Stephen Scott FRCP, FRCPsych

Professor of Child Health and Behavior, Director of National Academy for Parenting Research, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UK; Head, National Conduct Problems and National Adoption and Fostering Services, Maudsley Hospital, London, UK

Michael C. Seto PhD

Director of Forensic Rehabilitation Research, Royal Ottawa Health Care Group, Integrated Forensic Program, Brockville, Canada

Philip Shaw BM, BCh, PhD

Investigator, Social and Behavioral Research Branch, and Head, Neurobehavioral Clinical Research Section, National Human Genome Research Institute, Bethesda, MD, USA

Emily Simonoff MD, FRCPsych

Professor of Child and Adolescent Psychiatry, Department of Child and Adolescent Psychiatry, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UK and NIHR Biomedical Research Centre for Mental Health, King's College London, London, UK

David Skuse MD, FRCP, FRCPsych, FRCPCH

Chair of Behavioral and Brain Sciences, Institute of Child Health, UCL School of Life and Medical Sciences, University College London, London, UK

Patrick Smith PhD

Senior Lecturer and Honorary Consultant Clinical Psychologist, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UK

Anna T. Smyke PhD

Clinical Associate Professor of Psychiatry and Behavioral Sciences, Department of Psychiatry and Behavioral Sciences, Tulane University School of Medicine, New Orleans, LA, USA

Margaret J. Snowling PhD, Dip Clin Psych, FBA, F Med Sci, FBPSS

President, St John's College and Professor of Psychology, Department of Experimental Psychology, University of Oxford, Oxford, UK

Edmund J.S. Sonuga-Barke PhD

Professor of Psychology, Developmental Psychopathology and Director, Developmental Brain-Behavior Laboratory, Department of Psychology, University of Southampton, Southampton, UK
Guest Professor, Department of Experimental Clinical and Health Psychology, Ghent University, Ghent, Belgium

Matthew W. State MD, PhD

Oberndorf Family Distinguished Professor of Psychiatry; Chair, Department of Psychiatry; Director, Langley Porter Psychiatric Institute, University of California, San Francisco, CA, USA

Alan Stein MB, BCh, MA, FRCPsych

Head of Section, Child and Adolescent Psychiatry, Department of Psychiatry, University of Oxford, Oxford, UK

Argyris Stringaris MD, MRCPsych, PhD

Senior Lecturer, Head of Mood and Development Laboratory, Wellcome Trust Fellow, Department of Child and Adolescent Psychiatry, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UK
Consultant Psychiatrist, Maudsley Hospital, London, UK

Peter Szatmari MD, MSc, FRCP

Chief of the Child and Youth Mental Health Collaborative, Hospital for Sick Children, Centre for Addiction and Mental Health, Director of the Division of Child and Adolescent Psychiatry, University of Toronto, Ontario, Canada.

Tuula Tamminen MD, PhD

Professor of Child Psychiatry, Department of Child Psychiatry, University of Tampere and Tampere University Hospital, Tampere, Finland

Eric Taylor MA, MB, FRCP, FRCPsych, FMedSci

Emeritus Professor of Child and Adolescent Psychiatry, Department of Child and Adolescent Psychiatry, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UK

Anita Thapar MBBCH, FRCPsych, PhD, FMedSci

Professor of Child and Adolescent Psychiatry, Child and Adolescent Psychiatry Section, Institute of Psychological Medicine and Clinical Neurosciences, Cardiff University School of Medicine, Cardiff, UK

Kenneth E. Towbin MD

Chief, Clinical Child and Adolescent Psychiatry, Emotion and Development Branch, National Institute of Mental Health, Intramural Research Program, Bethesda, MD, USA
Clinical Professor of Psychiatry and Behavioral Sciences and Pediatrics, Psychiatry and Behavioral Health, The George Washington University School of Medicine, Washington, DC, USA

Hilary B. Vidair PhD

Co-Director of Clinical Training, Clinical Psychology Doctoral Program, Assistant Professor of Psychology, Department of Psychology, Long Island University, Post Campus, Brookville, NY, USA

Essi Viding PhD

Professor of Developmental Psychopathology, Faculty of Brain Sciences, University College London, London, UK
Professor of Cognitive Neuroscience, Institute of Psychiatry, Psychology and Neurosciences, King's College London, London, UK

Olga L. Walker PhD

Research Associate, Department of Human Development and Quantitative Methodology, University of Maryland, College Park MD, USA

Beth Watkins PhD

Clinical Psychologist, Feeding and Eating Disorders Service, Department of Child and Adolescent Mental Health, Great Ormond Street Hospital for Children NHS Foundation Trust, London, UK

Foreword

In the first edition of this textbook in 1976 the preface quoted the words of Sir Aubrey Lewis with respect to the need for psychiatrists to acquire “reasoning and understanding” and enable the combination of what he called “the scientific and humane temper” in his studies. That aspiration has been a continuous theme across the six editions of the textbook. That is, although a key part of what the textbook has provided has been current knowledge on empirical findings, it has given at least as much weight to the concepts involved so that readers are in a better position to deal with new findings and new ideas as they come along. That typifies this sixth edition as much as it did the previous five. The chapters seek to provide an appropriate balance between the questioning approach that is essential in both science and clinical work and a positive style that provides useful guidance on how to proceed in clinical practice. I am delighted with the skilful way in which the new team of editors has succeeded in this task.

In planning how they would deal with this new sixth edition, the editors will have wanted to think about some of the changes that have taken place over time. Some of these preceded the last edition but were not fully recognized at that time but all have increased in importance since then. First, there has been the evidence that there is much more overlap among diagnostic categories than used to be appreciated. This is noted in the chapter on classification. Second, there have been numerous important developments in genetics – including the discovery of rare genetic mutations, the role of copy number variations, the multiple clinical pictures associated with any of the single genes that have been found, and the importance of gene–environment interactions. These are well covered in the chapter on genetics. Third, there is the appreciation that not only are most risk factors dimensional in their operation but so, too, most disorders are also dimensional. The field has struggled somewhat in knowing how to deal with dimensions as well as categories but the topic crops up in many of the chapters throughout the volume. Fourth, the new edition of the American Psychiatric Association’s (APA) Diagnostic and Statistical Manual (DSM-5) has been published. It provides some worthwhile advances over the last edition, but overall it has to be said that it is disappointing in not dealing adequately with many of the challenges. Thus, the huge number of diagnostic categories remains and so does the overlap among them. The field of personality disorders and that of addictions are particularly poorly dealt with, as discussed in the relevant chapters of the new edition. Brain imaging remains a crucially important research tool but, with respect to looking

at interconnectivity among brain regions, there is evidence of the artifacts that may derive from motion during the scanning. This is discussed in the chapter on imaging. Finally, there has been a proliferation in the guidelines produced by the National Institute of Health and Care Excellence (NICE) that are relevant to child and adolescent psychiatry. These are noted in the relevant chapters of clinical disorders.

While retaining the strengths of previous editions, the editors have been creative in introducing several new topics. Thus, there is a chapter on systems neuroscience that is highly informative, but which treats neuroscience as a way of providing an understanding on clinical issues, rather than a field of knowledge that is separate from that. Animal models have come up from time to time in previous editions but this time the editors were surely right to recognize that so much use is now being made of animal models (some sound and some not quite so sound) that what can and cannot be achieved through their use deserved fuller discussion (as in Chapter 12) in this new edition. It is particularly good that animal models are treated not as a separate topic but rather as part of broader research strategies.

From the outset, the textbook has sought to provide guidance on how to move from statistical associations to causal inferences and this has become a major topic in the field. As in the previous edition, there is a very informative chapter on what clinicians need to know about statistical issues and methods. In addition, however, there is a new chapter on evaluating interventions. This deals with the statistical challenges but does so in a way that is focused on the concepts that clinicians need to appreciate when reading accounts of randomized controlled trials.

Through several editions, there has been attention to cultural variations and to national differences in service provision and the time was clearly ripe to bring this together in a new chapter on global psychiatry. Psychosocial researchers have, on the whole, been rather reluctant to consider biological implications of the psychosocial environment, but the empirical findings across what is now quite a broad literature indicate that this is mistaken. The new chapter on biological aspects of environmental effects seeks to bring all of this together – pointing to its relevance for certain key clinical issues.

The topic of epigenetics has become somewhat of a flavor of the moment but there is extensive evidence now that epigenetic effects are observable across a broad range of species and that they may matter in terms of the effects of experiences. The new chapter dedicated to considering this topic in its own right succeeds admirably in outlining what is involved in a way that

is readily understandable to those who work outside of the laboratory.

Resilience had a clear place in the last edition of the textbook but the findings have grown over the years and the new chapter seeks to bring together the concepts, findings, and clinical implications of what might be involved in the mechanisms that underlie the huge individual differences in children's responses to all manner of adversities.

The clinical chapters and the chapters on treatments all provide updating on what is known but two new chapters are worth comment. There is no longer a chapter on psychodynamic treatments because, as the chapter on this topic in the last edition indicated, psychodynamic approaches are now reflected in a wide range of treatments and, to a substantial extent, relationship-based treatments are the natural successor to psychodynamic treatments. The new chapter on this topic discusses what these involve and also indicates the ways in which they may be employed clinically. School-based mental health interventions are dealt with in another new chapter.

Again, they played a part in earlier editions but the time was ripe to consider them more fully on their own.

I greatly welcome this new edition as providing both a continuity with the past and a substantial, and extremely helpful, new look. As with previous editions, the breadth and strength of the editorial team has meant that all chapters have been peer reviewed by several, usually all, editors. This was the case last time and it remains a distinctive feature of the textbook. Not only do the editors provide a wide and varied range of clinical expertise but they provide scientific excellence. For example, most are active members of the relevant national scientific academies. I have been generously invited to contribute some chapters, but I have been happy to step aside from involvement in the editorship because I had such confidence that the new team of editors would do a great job, and clearly they have. I was pleased with the last edition but I think that readers will see that the quality of the sixth edition is actually superior to that of its predecessor.

Michael Rutter

Preface

Rutter's Child and Adolescent Psychiatry is an internationally leading textbook in our field. We have felt enormously privileged to have been entrusted with the role of lead editors for this new edition. It has been an exciting, instructive, and, sometimes challenging journey that has led us to the final version of this edition. We have been very fortunate that throughout the process we have had unfailing support and advice from Michael Rutter. We are very grateful to him for his help and have strongly appreciated his commitment and confidence in us.

Michael Rutter initiated a rigorous editing approach for the last edition that involves all chapters including initial outlines being peer-reviewed by the editors. The chapters cover a huge breadth of topics, and this process simply could not have been achieved without a team of skilled international editors. We have worked as part of a wonderful editorial team: James Leckman, Stephen Scott, Maggie Snowling, and Eric Taylor, who have a breadth of diverse interests, backgrounds, and experiences.

This textbook has relied on contributions from internationally outstanding experts. We are extremely grateful to all the contributors who have so readily engaged with the editorial team. It has been a pleasure to work with the authors of the chapters.

We have sought to maintain the very high standard set by the earlier editions, retain the conceptual and developmental aspects of the book as well as the strong clinical chapters, but also introduce some important changes. New chapters include those on systems neuroscience, using experimental models in humans and animals to study causal hypotheses and evaluating interventions, global psychiatry, epigenetics, resilience, relationship-based treatments, and school-based mental health interventions. The timing of the textbook means that Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) changes are also covered.

Finally, we thank Caroline Warren at Cwm Taf University Health Board, who has worked with all the editors, overseen the organization, and provided all the administrative support for this book. We have been tremendously grateful for her commitment, hard work, and organization.

Anita Thapar and Daniel S. Pine

PART I

Conceptual issues and research approaches

A: Developmental psychopathology

CHAPTER 1

Development and psychopathology: a life course perspective

Barbara Maughan¹ and Stephan Collishaw²

¹MRC Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, Psychology and Neuroscience, King's College London, UK

²Institute of Psychological Medicine and Clinical Neurosciences, Cardiff University School of Medicine, UK

Introduction

A life course perspective is central to developmental psychopathology. Michael Rutter and Alan Sroufe, founding fathers of the discipline, argued this need from the outset (Sroufe & Rutter, 1984; Rutter & Sroufe, 2000), and the intervening decades have amply confirmed their view. Longitudinal research has consistently demonstrated that most adult disorders have roots in childhood difficulties, and most childhood disorders have sequelae that persist to adult life. In mapping these long-term linkages, developmental findings have challenged etiological assumptions, highlighted unexpected connections across the life course, and raised key questions about the mechanisms—biological, psychological, and social—that underlie continuity and change.

Numerous insights have flowed from adopting a life course view. It is now clear, for example, that the burden of psychiatric disorders begins early in development. Disorder onsets fall into distinctive groupings (Angold & Egger, 2007), but most occur in childhood and adolescence. Some—such as the neurodevelopmental disorders—emerge very early in childhood; some—such as depression—show a sharp rise in the teens; and some—schizophrenia being the most obvious example—though typically emerging later in development have clear precursors in the childhood years. These differing onset profiles point to differences in underlying mechanisms. Developmental neuroscience is beginning to map the delays and perturbations in brain development characteristic of specific childhood disorders (Shaw *et al.*, 2010); to clarify the effects of stress exposure at different stages in the life course (Lupien *et al.*, 2009); and to highlight how both the pre- and postnatal environments affect epigenetic programming, with the potential for pervasive influences on the developing brain (Kofink *et al.*, 2013).

Long-term studies have also documented the strikingly high cumulative prevalence of mental health problems in the first two decades of life. Cross-sectional surveys identify around 10–12% of young people as disordered at any particular point in time; repeated longitudinal assessments, by contrast, suggest that well over 50% of young people will meet criteria for at least one psychiatric disorder by age 21 (see e.g. Copeland *et al.*, 2011). Looking backwards from adulthood, early vulnerability to adult disorder is equally clear; one follow-back study found that half of those with treated mental health problems in early adulthood had first met criteria for disorder by age 15 (Kim-Cohen *et al.*, 2003). Underlying these general linkages, developmental findings reveal a complex mix of continuities and discontinuities, and evidence of both *homotypic* prediction—the persistence or recurrence of the same disorder in different developmental periods—and apparently *heterotypic* transitions, where earlier and later vulnerabilities differ in form. Early emotional and behavioral difficulties also foreshadow a broad spectrum of problems in adult social functioning; poor physical health and health-related behaviors; poor economic circumstances (Goodman *et al.*, 2011); and, in some instances at least, an increased risk of early death (Jokela *et al.*, 2009).

Identifying the processes that underlie these differing pathways is central to the developmental psychopathology approach (Sroufe & Rutter, 1984). This chapter draws together evidence of this kind, using findings on selected disorders and early risks to highlight current issues in the field. Because tracing long-term developmental linkages poses particular methodological challenges, we begin with a brief overview of methodological issues, highlighting the strengths and limitations of differing research designs in identifying life course pathways, and the new techniques now available to investigators to delineate developmental mechanisms in longitudinal research.

Methodological considerations

Research designs

Optimal research designs vary with the question of interest. Robins' classic study of child guidance patients (Robins, 1966) is a landmark example of a "catch-up" study, designed to examine long-term outcomes of childhood conduct problems. Identifying her sample from child guidance records, Robins traced and interviewed prior clinic attenders in adulthood, gaining a broad picture of strengths as well as difficulties in their later lives. She used a general population sample from the same geographical area as a comparison group, and also paid attention to differences in outcomes within the treated group. The findings proved hugely influential: diagnostic criteria for Antisocial Personality Disorder were largely shaped by her findings, and the study generated numerous other developmental hypotheses that have stood the test of time.

Prospective studies of non-referred samples provide for a variety of extensions to this approach. First, they can include research-based assessments from the outset, allowing more nuanced tests of the early features most important in influencing later outcomes. Second, because they can include multiple assessment waves, they allow better tests of the timing and patterning of difficulties as they unfold over time. And third, they offer better opportunities to test hypotheses about possible causal mechanisms. Numerous studies have now used strategies of this kind; to take just one example, Laub and Sampson's (2003) long-term follow-up (to age 70) of the Gluecks' juvenile delinquency sample has been especially informative on the role of adult experiences, showing how both negative and positive experiences continue to shape developmental trajectories well into adult life.

Prospective studies of non-referred, population-based cohorts share many of these advantages, but have additional strengths: they are unaffected by referral biases; they can examine effects of environmental risk exposures; and they can also be used to study outcomes of dimensionally-defined behaviors or traits. Follow-back analyses tracing the childhood histories of individuals with particular later outcomes can also be derived from epidemiological/longitudinal data. Alongside these strengths, there are, of course, potential limitations. Some level of attrition is almost inevitable in long-term follow-ups, and may affect the representativeness of the retained samples; in addition, changes in diagnostic criteria may mean that study definitions devised in one era do not map precisely to more recent conceptualizations of disorder. The strengths of this design are, however, well attested by the extensive insights that continue to emerge from key epidemiological/longitudinal studies, including the Dunedin (<http://dunedinstudy.otago.ac.nz/>) and Christchurch (<http://www.otago.ac.nz/christchurch/research/healthdevelopment/>) studies in New Zealand, the Great Smoky Mountains Study in the United States (<http://devepi.duhs.duke.edu/gsms.html/>) and the Avon Longitudinal Study of Parents

and Children (ALSPAC) in the United Kingdom (<http://www.bristol.ac.uk/alspac>). Biomarkers are now frequently collected in longitudinal studies of this kind; prenatal influences are being investigated in studies beginning in pregnancy; and longitudinal twin studies are increasingly being used to document stability and change in genetic influences across development.

For some research questions, other designs are valuable. Studies of the very early precursors of disorder, for example, can capitalize on high-risk designs, tracking children selected on the basis of family or genetic risk. Lyytinen *et al.*'s (2008) prospective study of babies in families with dyslexia, for example, obtained detailed cognitive and neurophysiological measures from very early in development, identifying hypothesized precursor deficits well before children were exposed to the demands of learning to read. High-risk designs can also be used to assess long-term outcomes of early adversities such as maltreatment or early institutional deprivation, allowing both for tests of environmental risk mediation and contributors to variations in outcome within high risk groups.

Retrospective and prospective measures

In general, "prospective," contemporaneous measures of childhood behaviors or experiences are almost always preferable to retrospective reports of childhood collected in adult life. People are much better at remembering *whether* something happened than exactly *when* it occurred, and memories of the temporal ordering of events or behaviors—often required to test causal hypotheses—are especially open to bias. Retrospective reports of the age of onset of anxiety disorders, for example, seem heavily influenced by the age at which respondents are questioned (Beesdo *et al.*, 2009), and estimates of the lifetime prevalence of a number of common disorders are markedly higher when calculated from prospective rather than retrospective reports (Moffitt *et al.*, 2010). For memorable, easily defined events such as parental divorce or the timing of menarche, retrospective recall seems unlikely to be problematic (Hardt & Rutter, 2004). Deliberate falsifications are probably uncommon, and the main source of bias seems to arise from individuals who are functioning well in adulthood forgetting or underreporting early risk exposures, rather than those with poor outcomes exaggerating early adversities. Some events—such as early exposure to sexual or physical abuse—cannot usually be assessed in non-referred samples in childhood on ethical grounds, so much of what we know about their long-term implications is inevitably based on retrospective reports. Where comparisons with prospective data have been feasible, some have found very similar associations with risk for later disorder (Scott *et al.*, 2012), while others have not (Widom *et al.*, 2007); other evidence suggests that measurement errors in retrospective reports of child maltreatment have a quite limited influence on associations with later mental health (Fergusson *et al.*, 2011). As a result, although prospective data are to be preferred whenever feasible, it is

important not to exaggerate the problems of retrospective reporting, and to appreciate that there are circumstances where it is the only strategy realistically available. Finally, it is of course worth remembering that most “prospective” studies actually involve an element of retrospective reporting, reflecting events or behaviors occurring between study assessments.

Statistical methods for longitudinal research

Many long-term studies now include multiple assessments spanning long periods of the life course. To optimize the value of these rich resources, a range of specific statistical techniques has been developed (see Chapter 15). Some (such as multiple imputation) are designed to deal with problems of attrition; some (such as latent variable models) provide approaches to handling the complexity of both environmental and genetic risks for child mental health; and some (including structural equation modeling and cross-lagged panel analyses) provide tests of hypothesized mediating mechanisms and bidirectional effects. Arguably the most prominent recent developments, however, are methods that explicitly model patterns of stability and change over development, including group-based trajectory modeling, used to identify sub groups within the population that differ in their developmental course (Nagin & Odgers, 2010). First widely used in longitudinal studies of antisocial behavior, group-based modeling of this kind has since been applied to a wide range of phenomena, from pathways in early reading development (Lyytinen *et al.*, 2006) to trajectories of common mental health symptoms across the life course (Colman *et al.*, 2007). Trajectory modeling provides a direct means of testing etiological influences on sub groups with distinct developmental profiles, and can also be used to evaluate variations in intervention response.

Childhood–adulthood continuities

We turn now to examine life course findings in selected disorder groups. Detailed discussions of these disorders are presented in later chapters. Our aim here is to use emerging findings to illustrate more general developmental issues, focusing in particular on patterns of childhood–adulthood continuity. To begin, we focus on homotypic continuities in four selected disorder groupings (antisocial behaviors, depression, anxiety and exemplar neurodevelopmental disorders), chosen to reflect differing patterns of disorder onset and course. Following this, we explore the more complex heterotypic continuities identified in so much longitudinal research.

Antisocial behavior

Antisocial behaviors and delinquency were among the first aspects of child behavior to attract attention from longitudinal researchers; as a result, a good deal is now known about their basic developmental profiles and course (see Chapter 65).

Many indicators of antisocial behavior show highly distinctive age-related trends: physical aggression, for example, is at its peak very early in childhood (Tremblay, 2010), while delinquency rises sharply across the teens, declining gradually in the early adult years. In addition, longitudinal data consistently highlight the paradox that while most severely antisocial adults were antisocial children, only perhaps half of antisocial children go on to show marked antisocial behavior in adult life (Robins, 1966).

These findings point to heterogeneity in the antisocial population, and a number of approaches to subtyping have been proposed (Lahey & Waldman, 2012). Moffitt’s (1993) developmental taxonomy highlights age at onset as the core distinguishing feature; other well-established markers of heterogeneity include comorbidity with ADHD, distinctions between physically aggressive and non-aggressive behaviors, and the presence of associated callous-unemotional (CU) traits (see Chapter 68). Considered individually, each of these features predicts long-term continuities in antisocial behavior; investigators are still working to clarify whether they constitute different facets of a single high-risk sub group or separable associated risks.

A further striking feature of longitudinal findings in the antisocial field is the wide spectrum of adverse outcomes faced by young people with disruptive behavior problems later in their lives. Fergusson *et al.* (2004), for example, found that (in addition to continuities in antisocial behavior), childhood conduct problems were associated with poor educational and occupational achievements; problems in sexual and partner relationships; early parenthood; and elevated rates of substance use, mood and anxiety disorders, and suicidal acts. Subsequent studies have documented associations with poor health-related behaviors and markers of chronic disease early in adulthood (Odgers *et al.*, 2008) and later—in representative as well as high risk samples—with increased risk of premature death (Maughan *et al.*, 2014).

What accounts for this broad spectrum of adverse outcomes? First, genetic liabilities are almost certain to play some part. Longitudinal twin studies point to genetic continuity in general antisocial phenotypes from late childhood to early adulthood, along with new genetic (and environmental) influences in adolescence (Wichers *et al.*, 2013). In addition, early onset conduct problems, physical aggression, and CU traits—all of which carry high risks of persistence—are all strongly heritable. At the same time, child conduct problems are also strongly associated with adverse environmental conditions. Studies of gene–environment interplay highlight the complex ways in which genetic and environmental factors combine to impact risk for the persistence of disorder over time. On the one hand, genetic factors may *moderate susceptibility* to individual and family-based risks (see Chapter 24). In the Christchurch longitudinal study, for example, variations in the MAOA genotype interacted with factors as varied as maternal smoking in pregnancy, material deprivation, maltreatment, and lack of school-leaving qualifications to influence risk for adolescent and early adult offending (Fergusson *et al.*, 2012).

On the other, genetically influenced traits may affect *exposure* to adverse environments. It has long been known, for example, that aspects of children's temperament and behavior can evoke negative reinforcing responses from parents. Evidence is now emerging that similar processes occur with peers: as early as the kindergarten years, genetically-influenced hyperactive and disruptive behaviors can evoke peer victimization and rejection (Boivin *et al.*, 2013), while later in development, genetic factors contribute to affiliations with deviant peers (Kendler *et al.*, 2007). Across development, cumulating consequences of this kind can function to stabilize maladaptive behaviors, selecting antisocial young people into risk-prone environments, and restricting their opportunities for involvement in more positive relationships and roles.

For children with early onset conduct problems, developmental "cascades" of this kind seem likely to contribute in important ways to the persistence of antisocial behavior over time. Where adolescent onset problems persist, substance abuse has been highlighted as one especially salient "snare" that can hinder desistance from offending (Husong *et al.*, 2004). In addition, antisocial young people may vary in the extent to which they have access to, or can benefit from, later positive experiences. Sweeten *et al.* (2013), for example, identified changes in antisocial peer affiliations and peer influence as among the strongest correlates of reductions in offending among adjudicated offenders, while Laub and Sampson (2003) highlighted the role of adult "turning point" experiences, including social attachments to work, and supportive marital relationships, in promoting desistance from crime. The great majority of offenders eventually desist; these findings point to intervention targets that may accelerate that process and help to break—or at least interrupt—chains of risk.

Depression

Developmental findings have also been salient in relation to depressive disorders, markedly changing conceptualization of depression over time. Before the 1980s many viewed depression as a predominantly adult disorder: pre-pubertal children were thought too immature to experience depressive disorders, and adolescent low mood was assumed to reflect normative teenage mood swings. A wealth of evidence from clinical and epidemiological studies has changed these views. It is now clear that, though uncommon (1–2%), depressive disorders do occur in pre-pubertal children, and that depressive-like phenomena are also observed in some children as early as the preschool years (Angold & Egger, 2007).

Despite these early manifestations, adolescence is now recognized as a particularly important life stage in the development of depression. First, rates of depression increase markedly across the adolescent years, with median 12-month prevalence estimates equivalent to those for adults (4–5%), and a cumulative prevalence as high as 20% across the teens. New onsets of major depressive disorder continue across the life course, but for many sufferers the disorder begins in the adolescent years.

Second, unlike childhood depression, adolescent depression shows strong continuity to adulthood; in referred young people, initial remission is followed by a recurrence in around 50–70% of patients within 5 years (Thapar *et al.*, 2012). And third, the female preponderance typical of adult depression becomes clearly established in the teens. The emergent sex difference seems more closely linked to pubertal stage than chronological age, pointing to the likely role of hormonal factors (Angold *et al.*, 1999); sex differences in adolescent brain development and in the cognitive processing of stressful experiences may also contribute to rising rates of depression in girls (Hyde *et al.*, 2008).

Depressive disorders in childhood, adolescence, and adulthood are typically defined by the same underlying features; despite this, it remains unclear whether depression at these different ages does indeed reflect a single homogenous disorder or common etiology. Childhood depression differs from adolescent and adult depression in a number of important ways: the prevalence is lower, there is no marked gender difference, and continuity with adult depression is low. There are also important etiological differences, with twin studies demonstrating consistently lower heritability for depression in children than in adolescents or adults. Distinctions between adolescent and adult depression are less clear. Studies comparing the psychosocial risk profiles of "juvenile"- and adult-onset depression suggest that early adversity, parental neglect, and problematic peer relationships are more strongly associated with early-onset depression (Jaffee *et al.*, 2002). Others have argued, however, that such findings reflect recency of risk exposure, and that developmentally-salient stressors are associated with depression at all stages of the life-course (Shanahan *et al.*, 2011). Treatment responses also show developmental variation, with tricyclic antidepressants effective in adult but not in child or adolescent depression (Hazell *et al.*, 2002). It remains unclear whether these differences in risk correlates and treatment response reflect maturation of relevant neurobiological systems, heterogeneity in the underlying nature of depression, or stage of illness factors.

Given the high rates of recurrence in depression, studies of the mechanisms underlying continuity across developmental periods are especially important. Heritable factors clearly play a part here, contributing to stability in depressive symptoms in both adolescence and adulthood (Lau & Eley, 2006). In addition, extensive evidence suggests that—as with antisocial behavior—genes act in concert with environmental influences to increase both *susceptibility* to psychosocial stressors (gene–environment interaction) and *exposure* to stressful environments (gene–environment correlation). Maladaptive coping styles such as rumination, depressogenic cognitive biases, and difficulties in interpersonal relationships are both predictors and outcomes of depression, forming further contributors to recurrence risk (Abramson *et al.*, 2002). And finally, vulnerability to relapse and illness severity appear to increase across the course of depressive illness, becoming increasingly autonomous from severe precipitants as the number of episodes increases (Kendler *et al.*, 2000). Often referred to as "kindling," processes of this

kind suggest that depression itself may increase sensitivity to stress, so that in time even relatively minor everyday stressors can trigger a recurrence (Post, 2010; but see also Monroe & Harkness, 2005).

As these findings suggest, developmental studies have provided important insights into influences on both onset and recurrence of depression. More evidence is now needed on factors that distinguish young people with more and less benign courses of early illness, to maximize the contribution of developmentally-sensitive findings for prevention and treatment.

Anxiety disorders

Different issues arise in relation to anxiety disorders, stemming in large part from the complexities of current nosology, where numerous different anxiety diagnoses are defined. Debate continues over the utility of this approach, and whether other distinctions—derived, for example, from neuroscience frameworks—could provide a more appropriate basis for classification (Pine, 2007). Developmental findings can contribute to these debates.

Beginning with age at onset, it is now clear that there is meaningful heterogeneity in onset patterns among anxiety diagnoses: some typically onset in childhood, some in early adolescence, and some in late adolescence/early adulthood. Separation anxiety and specific phobias have the earliest onset ages; in the German Early Developmental Stages of Psychopathology (EDSP) study, 50% of these disorders had begun by ages 5 and 8 years respectively, and almost all cases had emerged by age 12 (Beesdo-Baum & Knappe, 2012). Rates of social phobia and OCD (obsessive compulsive disorder) rose sharply in early adolescence, while agoraphobia, panic disorder, and GAD (generalized anxiety disorder) became more common later in adolescence and early adulthood. These later onset disorders lack the circumscribed fears seen in childhood onset disorders, possibly indexing a developmental shift in the expression of anxiety with age, and raising intriguing questions about the mechanisms involved.

Much less diagnostic specificity is evident in findings on developmental course. Retrospective studies point to the persistence of early anxiety disorders and suggest a relatively chronic or recurrent course (see e.g. Kessler *et al.*, 2012). Prospective findings paint a rather different picture; while they confirm above-chance levels of homotypic continuity, they also report quite low rates of stability in specific anxiety diagnoses and—especially in younger age groups—a tendency for anxiety symptoms to wax and wane over time (Bittner *et al.*, 2007; Beesdo-Baum & Knappe, 2012). Onset of a first (“pure”) anxiety disorder is often followed by the development of other anxieties in adolescence/early adulthood; in its turn, this “load” of anxiety predicts other adverse outcomes including depression, substance use, and suicidality, along with psychosocial difficulties and poor health and relationship functioning (Copeland *et al.*, 2014).

Follow-back findings from the Dunedin study (Gregory *et al.*, 2007) are broadly consistent with this view, with little specificity in the childhood–adulthood linkages involved; specific phobias in adulthood had a significant history of juvenile phobias, but other adult anxiety disorders were likely to have been preceded by a range of anxiety diagnoses. Alone among DSM-IV adult anxiety diagnoses, PTSD stood out in having a history of behavioral as well as emotional difficulties earlier in development (Koenen, 2010); in conjunction with other individual and family factors, these early influences appeared to play a key role in shaping both exposure and responses to trauma later in life. Finally, we note that recent evidence is providing empirical support for one pattern of childhood–adult continuity of longstanding clinical interest: the possibility that separation anxiety in childhood may be a precursor to panic disorder later in life. Rates of separation anxiety fall sharply in the early teens, but a recent meta-analysis has identified a significant association with later panic (Kossowsky *et al.*, 2013), and longitudinal twin study findings have identified a common genetic diathesis between separation anxiety disorder and panic attacks (Roberson-Nay *et al.*, 2012).

Relatively little is known about the mechanisms that contribute to the persistence or recurrence of anxiety across development. Twin studies point to genetic influences on stability, but also highlight more “developmentally dynamic” patterns, with attenuation of the genetic effects on some late childhood anxiety phenotypes by early adulthood, along with the emergence of new genetic influences later in development (McGrath *et al.*, 2012). In a follow-up of social anxiety disorders from adolescence to early adulthood, Beesdo-Baum and colleagues (2012) identified earlier age at onset, severity of avoidance, impairment, and a high number of catastrophic cognitions as associated with persistence and diagnostic stability. Established risk factors for the onset of anxiety disorders, including both behavioral inhibition and a family history of social phobia or depression, also signaled a poorer prognosis.

Behavioral inhibition is a strong risk factor for the development of anxiety disorders, and social anxiety in particular (Clauss & Blackford, 2012; see Chapter 8). A variety of environmental factors have also been implicated, including maternal personality, aspects of the mother–child relationship, and an oversolicitous, intrusive, or controlling parenting style (Degnan *et al.*, 2010). Evidence is now emerging that parenting can moderate temperamental vulnerabilities, with risks for anxiety disorders especially marked when behavioral inhibition occurs in the context of parental over control. Biased attention-orienting to threat—a well-established concomitant of many anxiety disorders—also appears to modulate associations between inhibition and disorder (Shechner *et al.*, 2012). In addition, aspects of the peer context may moderate, maintain, and possibly exacerbate temperamental influences (Degnan *et al.*, 2010). Inhibited children tend to be less socially competent than their peers; as a result, they are more likely to be excluded from peer groups, and may be targets of bullying—both factors

known to increase risk of anxiety disorders. To date, interpersonal processes of this kind have primarily been documented in early and middle childhood. We must await further evidence to determine how far similar relational processes occur later in the life course, amplifying the effects of early temperamental characteristics and increasing vulnerability to the persistence of anxiety beyond the childhood years.

Neurodevelopmental disorders

We conclude with a brief overview of the rather different issues raised by current findings on outcomes in some of the earliest onset disorders of childhood: the neurodevelopmental disorders. As discussed in Chapter 3, and in the individual disorder chapters, extensive effort continues to be devoted to improving our understanding of the etiology of these complex difficulties. Evidence on later outcomes is much more sparse, but current findings leave little doubt that neurodevelopmental disorders are lifelong conditions. In general, some diminution in core symptoms seems typical with age, but alongside this it is also clear that broader functional impairments persist at least to adolescence, and often to adult life. We focus here on findings in just two areas—autism spectrum disorders (ASDs) and ADHD—to illustrate some of the issues that arise.

Beginning with autism, a recent review of follow-ups to early adulthood (Howlin & Moss, 2012) concluded that although the severity of symptoms tends to decrease with age, adult outcome is very mixed, including for individuals with normal IQ. One of the longest-term follow-ups to date (Howlin *et al.*, 2013) found some improvements in core symptoms and language skills by middle adulthood, but psychosocial outcomes were often poor, and in some instances appeared to have deteriorated over time. Over half in this sample had never worked, or were long-term unemployed; the majority had little autonomy in terms of daily living; and most had no close friend. The samples studied to date were, of course, diagnosed some decades ago, before early interventions and specialist educational supports were generally available, and when only more severely affected children were likely to receive a diagnosis. Outcomes for young people with ASDs today may be more promising; current findings can still, however, provide important pointers to factors that underlie variations in long-term outcomes. Early difficulties in reciprocal social interaction appear to be important here (Howlin *et al.*, 2013), along with the extent and severity of core symptoms, the extent of cognitive impairment, and the presence of co-occurring psychopathology. Environmental supports may also be crucial; indeed, some reports suggest that lack of appropriate support in adulthood can have a more deleterious effect on outcomes than factors such as IQ. The transition to adulthood raises new and potentially difficult psychosocial challenges for many individuals with ASDs, yet appropriate support services in adulthood are often severely lacking. Recent years have seen major advances in the development of comprehensive diagnostic and intervention services for young children with

autism; findings from long-term studies point to the need for equally effective interventions across the life span.

Evidence on adult outcomes of ADHD is more extensive, though again few studies have tracked samples beyond the early adult years. Most children with ADHD show persistence of symptoms in adolescence and adulthood, with inattentiveness slower to decline with age than hyperactivity/impulsivity. A meta-analysis of follow-up findings (Faraone *et al.*, 2006) showed that although only around 15% met full criteria for disorder in early adulthood, a further 50% continued to face impairments associated with residual symptoms. In addition, follow-up studies highlight a strong persistence of earlier conduct problems in children with ADHD, as well as new onsets of antisocial behavior and substance misuse in adolescence (Langley *et al.*, 2010a); heightened risks for health risk behaviors in adulthood (Olazagasti *et al.*, 2013); and a range of negative educational, occupational, and psychosocial outcomes that appear to persist at least to mid life (Klein *et al.*, 2012). Even when ADHD is diagnosed and treated, only a minority of individuals subsequently exhibit full functional and symptomatic recovery.

The persistence of symptoms and later impairments seems especially marked in those with co-occurring conduct disorder/antisocial behavior; in addition, initial severity, IQ, and poor childhood school and social functioning have also been found to predict persistence, as have parental psychopathology and family conflict (Cherkasova *et al.*, 2013). Despite continuing needs, clinical recognition and service provision in adulthood remains limited, and individuals with ADHD are often reported to become disengaged from services and treatment. Increasing awareness of the lifelong consequences of ADHD, improved transitions from child to adult mental health services, and continued support in adulthood are all increasingly underlined as important priorities (Young *et al.*, 2011).

As these brief overviews suggest, evidence from differing neuro-developmental disorders highlights that adult outcomes for affected individuals are often poor. The stability of core symptoms varies, and may indeed show some improvements with age; alongside this, however, effects on psychosocial functioning may be more marked in face of the more complex demands of adolescence and adult life. Current evidence points to the benefits of supportive social contexts in adulthood, and the crucial need for continuing, appropriate services for many individuals with neurodevelopmental conditions.

Heterotypic transitions and psychopathological progressions

In addition to these “homotypic” continuities, developmental studies also make clear that more complex, “heterotypic” transitions among apparently distinct disorders are far from uncommon. Because multiple disorders often co-occur, some of these observed associations may be “epiphenomenal”—the product (at least statistically) of associations among other disorders. As a result, the strongest basis for identifying

“independent” heterotypic transitions among disorders comes from prospective, population-based studies that assess multiple disorders over time.

Copeland *et al.* (2013a) have recently reported findings of this kind, bringing together data from three major long-term studies to examine diagnostic transitions in common disorders from childhood to adolescence, and from adolescence to early adult life. Overall, continuities across developmental periods were strong, and bivariate analyses highlighted numerous heterotypic as well as homotypic links. Once prior “comorbidities” were controlled, heterotypic linkages were less common, but still clearly emerged. Between childhood and adolescence, the most robust transitions were from ADHD to ODD (oppositional defiant disorder), and from both CD (conduct disorder) and depression to later substance use. Between adolescence and adulthood, depression, and anxiety cross-predicted; adolescent substance use predicted early adult depression; and both CD and ADHD were associated with increased risks of later substance disorders. Predictions from CD to internalizing disorders were not supported in adjusted analyses; predictions from adolescent ODD to early adult depression fell just short of significance. Copeland *et al.* (2013a) were not able to examine transitions within the years of childhood, or between more common disorders and either neurodevelopmental problems or schizophrenia. From other evidence, however, it seems likely that early transitions from ADHD to CD, associations between schizophrenia and earlier emotional/behavioral difficulties, and the emergence of emotional/behavioral difficulties in children with specific learning problems should be added to this list of “independent” heterotypic progressions.

How might patterns of this kind arise? Two broad types of explanation have been put forward: that heterotypic continuities reflect age-varying expressions of the same underlying liability, or that one disorder or its associated impairments constitute risk factors for a second, distinct condition. In practice, elements of both processes may often be involved and shared genetic vulnerabilities implicated. Behavior genetic analyses have consistently identified shared genetic influences on pairs of disorders; more recently, multivariate genetic studies have highlighted more widespread genetic pleiotropy, suggesting that most common forms of child psychopathology share some genetic liabilities (see e.g. Lahey *et al.*, 2011). It is also becoming clear that specific molecular genetic risk factors operate across different disorders (Owen *et al.*, 2011; see Chapter 24). From a developmental perspective, findings of this kind may suggest that the same genetically-based vulnerabilities are manifest in different ways at different stages in development, in part, perhaps, as a result of interactions with normative maturational processes or changes in young people’s social worlds. Investigators are now beginning to identify heritable neurobehavioral vulnerabilities that may contribute to processes of this kind. In relation to progressions from childhood anxiety to adolescent depression, for example, changes in sensitivity to social evaluative threats around the time of puberty may constitute intermediate

phenotypes of this kind (Silk *et al.*, 2012). Emerging evidence suggests that the brain systems involved in responding to social information may become more sensitive or active during puberty—a time when peer and romantic relationships are also growing in importance, and when social evaluations become increasingly salient. If confirmed, models of this kind not only move us closer to understanding how genetically-based vulnerabilities may contribute to transitions among disorders, but may also suggest new targets for intervention.

The value of examining pathways of this kind has also emerged in studies of progressions from ADHD to conduct problems. Here, replicated evidence has shown that the *COMT* val158met variant high-activity genotype is associated with increased risk for antisocial behavior specifically in the presence of ADHD (Caspi *et al.*, 2008). This gene variant has well-established associations with executive functioning, and also with problems in social cognition—both known correlates of antisocial behavior, and both thus plausible intermediate phenotypes. Langley *et al.* (2010b) tested both as potential mediators in the ALSPAC cohort; problems in social understanding were on the pathway from genotype to antisocial outcomes in children with ADHD, while measures of executive control were not. Once again, these findings may have clinical as well as theoretical significance, suggesting that interventions to improve social understanding in ADHD may reduce risks of the development of aggression and conduct problems.

Conduct problems figure prominently in reports of heterotypic continuity; indeed, follow-back analyses of early adult disorders in the Dunedin cohort showed that CD/ODD was part of the developmental history of *all* the young adult disorders assessed, including manic episodes and schizophreniform disorders (Kim-Cohen *et al.*, 2003). Progressions from CD to substance use are among the best-established associations, likely reflecting shared, genetically-based personality features. Here, however, associations are not simply unidirectional: CD predicts adolescent substance use, but early adolescent alcohol and cannabis use also predict subsequent delinquency. Mediating mechanisms appear to vary at different stages of substance use, with, for example, shared environmental influences most important for transitions to early alcohol use, but shared genetic liability the dominant influence on links between antisocial behavior and later alcohol dependence (Malone *et al.*, 2004). Once established, substance problems may affect persistence in antisocial behavior through a variety of pathways including neurobiological effects on disinhibition, peer influences, adverse effects on family relationships, and the need for money to support drink and drug habits.

In addition to progressions to other “behavioral” disorders, child and adolescent conduct problems have also frequently been associated with increased risk for depression. To date, progressions of this kind have largely been assumed to reflect “down stream” effects of conduct problems, whether via selection into stress-prone environments, the development of negative

self-cognitions, or, in some instances, the pharmacological effects of substance use. Recently, however, studies have begun to highlight the possibility of shared temperamental influences centering on irritability. Longitudinal findings suggest that ODD, rather than CD, may be the more salient predictor of depression risk (Copeland *et al.*, 2009), with irritable mood a key element in this progression; adolescent irritability has also been found to predict suicidality later in adulthood (Pickles *et al.*, 2010), and twin studies point to common genetic underpinnings with low mood (Stringaris *et al.*, 2012; see Chapter 5).

As these examples suggest, many developmental associations among apparently distinct disorders may in part at least reflect expressions of the same underlying liability. Some, however, do seem likely to reflect *psychopathological progressions*, whereby the experience of one disorder contributes, directly or indirectly, to risk for another. Though evidence is still limited, some emotional/behavioral concomitants of specific learning difficulties may be of this kind; links between reading difficulties and anxiety, for example, show no clear evidence of shared genetic influence in the twin samples studied to date (e.g. Whitehouse *et al.*, 2009), suggesting that reading problems may constitute a direct risk for the development of anxiety in some children. Associations between substance use and later depression provide a second, quite different, example. Links between these disorders are strong, raising important questions over both the likely direction of effects and the causal processes involved. In the case of alcohol abuse disorders, a recent review and meta-analysis concluded that links with depression could not be attributed to confounders; that evidence was strongest for an effect of alcohol abuse on depression; and that potential mechanisms include neurophysiological and metabolic changes resulting from alcohol exposure (Boden & Fergusson, 2011).

Long-term effects of early experience

We conclude by examining a different aspect of childhood–adult “continuity”: links between adverse experiences early in development and risk for psychopathology later in life. The shorter-term sequelae of childhood adversities are examined in detail in Chapter 26. We focus here on evidence for their persisting impact beyond the childhood years; on issues involved in interpreting evidence on such long-term links; and on some of the intervening mechanisms that are likely to be involved.

There is by now extensive, well-replicated evidence of associations between exposure to early adversity and risk for both psychiatric disorder and poor physical health later in life. Both chronic stress and severe acute experiences seem implicated, spanning exposures as varied as maltreatment and neglect, maladaptive family relationships, parental psychopathology, depriving institutional rearing, bullying victimization, and socioeconomic disadvantage (Odgers & Jaffee, 2013).

Retrospective evidence for associations with adult outcomes comes from large-scale epidemiological surveys such as the Adverse Childhood Experiences (ACE) study (Dube *et al.*, 2001), where information on adult disease is linked to respondents’ recollections of childhood. Studies of this kind have shown strong links between childhood adversity and adverse health sequelae across the adult years (Odgers & Jaffee, 2013). Long-term prospective follow-ups of both high-risk and epidemiological samples are now confirming these findings in an increasing range of areas. Prospectively-reported childhood family adversities, extra familial adversities such as bullying, and follow-ups of abused and neglected children all show substantial predictive associations with psychiatric disorder in adult life (e.g. Copeland *et al.*, 2013b; Horwitz *et al.*, 2001).

The consistency of these findings is compelling; nonetheless, some caution is required in interpreting their meaning. Statistical associations do not, of course, necessarily imply causation. Shared genetic liabilities may contribute to children’s vulnerability to adverse experiences, but also to their exposure to them; as a result, associations between psychopathology and adversity may reflect reverse causation, or reciprocal influences that play out in complex ways over time (Sameroff & Mackenzie, 2003).

As discussed in Chapter 12, increasingly sophisticated analytic methods are now being applied to tease these differing possibilities apart. In some instances, evidence for causal influences has proved limited, once shared genetic and environmental confounders are taken into account. In others, correlated adversities may form elements in a causal chain, with, for example, the effects of distal risk factors such as poverty or parental divorce mediated via more proximal aspects of family functioning (Conger *et al.*, 1994). Early adversities rarely occur in isolation, and the clustering of adversities makes it difficult to identify unique risk effects. Traditionally, identifying specific influences has relied on multivariate statistical techniques, but these have inherent limitations; where possible, evidence from intervention studies, genetically sensitive designs and other quasi-experimental approaches provides for more powerful tests (see Chapter 12). Such approaches already provide evidence of the likely causal effects of a range of adversities on psychopathology in childhood; though currently more limited, genetically sensitive studies are also beginning to point to long-term causal influences (see e.g. Kendler & Gardner, 2001).

Studies are also clarifying other aspects of adversity–outcome associations. First, contrary to some early assumptions, most early adversities appear to show relatively nonspecific predictions to a broad range of later psychopathology (Gershon *et al.*, 2013), as well as impacts on cognitive development, educational, and occupational functioning, social relationships, and health (Odgers & Jaffee, 2013). Second, the effects of exposure to multiple adversities are cumulative. Childhood adversities often cluster, and negative adult outcomes are most common in those who experience multiple risks. In the ACE study, for example, the risk of suicide attempt was elevated 2–5 fold when individual childhood adversities were examined separately, but increased

up to 30-fold when the cumulative burden of adverse early experience was taken into account (Dube *et al.*, 2001).

Third, in relation to timing, it has been proposed that exposure to stress at critical periods of brain development may carry especially high risk for later psychopathology (Heim & Binder, 2012). In observational studies, however, it is difficult to identify discrete sensitive periods because so many risk exposures are chronic or recurring. At present there is little support for the notion that the risk effects of adversity are *confined* to particular sensitive periods, though there is evidence for developmental variation in risk effects. Studies of Romanian children adopted from extremely depriving institutions, for example, highlight not only that very early privation can have persistent deleterious effects on development, but also that age at placement is an important determinant of the degree of later impairment and post adoption catch-up (Rutter *et al.*, 2012).

Progress has also been made in identifying the range of mechanisms that may underlie the long-term effects of early adversity. Evidence on the biological embedding of early experience—how early adversity “gets under the skin”—is reviewed in detail in Chapter 23. Negative impacts may also be mediated via effects on cognitive, affective, and psychological development. Exposure to maltreatment, for example, has been shown to influence children’s emerging capacity to regulate emotions; to contribute to deficits and biases in processing affective stimuli; and to lead to problems in social information processing (Dodge, 2006). In addition, problems in close friendships and intimate relationships are also common, depriving individuals of the benefits of supportive relationships, and studies of adult victims of maltreatment highlight increased exposure to further adverse life events (including revictimization) in adult life.

In part, long term risk effects may also be mediated by effects on early-onset psychopathology, though current evidence suggests that this is unlikely to provide a complete explanation. Data from the Great Smoky Mountains Study, for example, demonstrate that victims of bullying experienced elevated rates of psychiatric disorder in childhood, adolescence, and adulthood; when earlier psychopathology was accounted for, however, associations with adult psychiatric disorder remained (Copeland *et al.*, 2013b).

Finally, a universal finding is that there is substantial heterogeneity in long-term outcome following all kinds of early adversity (Rutter, 2013). Despite exposure to enduring and severe early stressors, many children maintain adaptive trajectories and achieve positive outcomes later in life. Understanding resilience of this kind is important for two reasons: it can cast new light on developmental processes and may also point to additional foci for preventative interventions—“risk buffers”—that can be promoted to mitigate the impact of early trauma and adversity when amelioration or removal of risk is not feasible.

Resilience is an interactive concept, involving the better-than-expected outcomes achieved by some individuals in the face of early adversity (Rutter, 2012; 2013). The processes that explain resilience (see Chapter 27) are likely to be fluid, encompassing

varying psychological, social, and biological features at different stages in development. First, evidence of gene-environment interactions highlights that genetic factors play a role in moderating individual responses to stress. Second, psychological and cognitive processes are important; children differ in their perceptions and understanding of stressful and traumatic events, and those who do not attribute blame to themselves when parents separate, or in the context of maltreatment, are more likely to avoid negative psychological sequelae (McGee *et al.*, 2001). In addition, individuals’ personal agency, along with their capacity to self-regulate emotions and plan for the future, are consistently associated with mental health and psychosocial outcomes in high-risk groups. Third, resilience studies indicate that the maintenance of positive social relationships, both with family members and with peers, may be especially important in the context of early adversity (Collishaw *et al.*, 2007); and for some individuals, the transition to adulthood can provide opportunities for positive “turning point” experiences—such as marriage—that can disrupt previously maladaptive trajectories (Jaffee *et al.*, 2013). Fourth, there may be important context-specific predictors; for example, enhancing community support and reducing stigma are promising targets for intervention in communities affected by AIDS (Betancourt *et al.*, 2013; see Chapter 46). And finally, although evidence of “steeling” effects in humans is still preliminary (Rutter, 2012), in some circumstances exposure to mild forms of stress may prepare individuals for dealing with more difficult challenges later in life.

Conclusions

As these brief sketches illustrate, although complex, connections across the life course are meaningful and strong, and a life course perspective brings both scientific and practice-oriented insights that would remain hidden in more developmentally “demarcated” research. Over time, developmental studies have contributed to our etiological understanding, highlighted the heterogeneity in pathways (both adaptive and maladaptive) that follow from childhood disorder, and underscored the possibilities for resilience, recovery, and positive turning points that arise throughout development. Though some long-term studies were initiated many years ago, most are of much more recent origin. This “first generation” of longitudinal research has already provided rich rewards, transforming thinking in numerous domains; we can expect equally rich—and equally challenging—insights as results from the next generation of studies begin to emerge.

CHAPTER 2

Diagnosis, diagnostic formulations, and classification

Michael Rutter¹ and Daniel S. Pine²

Introduction

In essence, classification provides a standardized way of describing phenomena and thereby enabling communications about those phenomena to be possible because all concerned will use terms in the same way. However, classification is a multi-faceted endeavor and, therefore, we need to begin with a discussion of those different facets. After defining key terms, the current chapter delineates major questions that have emerged from prior research on these different facets. This is followed by a review of data on validity, as it informs classification. However, current data on validity leave many questions unanswered. As a result, the chapter closes by delineating the nature of these questions and setting an agenda for addressing them in future classifications schemes that go beyond the forthcoming revision of ICD and DSM-5.

Definition

The purpose of diagnosis is to indicate what each disorder, as evidenced in an individual, has in common with a similar disorder shown by other people. Two points need emphasis. First, it refers to a pattern of signs and symptoms, and *not* to people. It is scientifically misleading to suppose that a single designation could summarize all that is important about a person, and it is offensive to use terminology that implies the contrary. Accordingly, it is now preferred to refer to an individual *with* autism (or ADHD) rather than an autistic (or ADHD) person. This constitutes a reminder that it may be possible to relieve the symptoms without requiring that the person as a whole be radically changed. Cure (in the sense of completely eradicating a condition) is rare across the whole of medicine. Consider diabetes, coronary artery

disease, and asthma as examples in internal medicine. On the other hand, it may well be possible to restore sound functioning.

A diagnostic formulation is quite different from a diagnosis, in that only the former involves a discussion of the features that are particularly crucial in that person, even though they may not be so in other people. Such features do not just (or even mainly) concern signs and symptoms. Rather the focus may be on the hypothesized causal influences; the existence of protective features; the family and broader social context; and the range of considerations that need to be considered when planning how best to intervene. It should also end with a hypothesized causal nexus and a plan for care/treatment. Most crucially, it should spell out how the individual's response to the intervention can provide guidance on whether or not the postulated explanation was correct (and, if not, how it, and the treatment plan, should be modified). What this clearly means is that any adequate diagnostic formulation must extend well beyond the listing of signs and symptoms. Moreover, the formulation should provide an anticipated prognosis, together with guidance on how both the child and the family should deal with the problems. For these reasons, it has become best practice to provide each individual and family with a written feedback letter (or report), summarizing what was discussed at the assessment. This should include a brief summary of the basis for the decision-making, and the plans for what is to happen next.

Classification is a generic term that provides a standardized approach to communication, either among clinicians or researchers. Thus, classification is intended to ensure that when a clinical or research report states that, for example, the findings refer to a group of patients with, say, autism or ADHD, everyone will understand what this means and will use the diagnostic term in the same way. However, classification goes beyond individual diagnoses to consider how collections of diagnoses should

be grouped together, or placed in a cluster. Similarly, it will specify the extent to which diagnoses should be split into finer subdivisions, or lumped together with other diagnoses to form a larger grouping. Because this clustering is designed to inform decisions, which arise in many diverse contexts, this means that there can be no simple “right” way to construct a classification. Appropriate classification reflects the purpose at hand. For example, what works best at a primary care level may be much simpler than that which is required in a specialized research center. Also, the organization that is best for clinical purposes (such as for prognosis or planning treatment) may differ from that which is mainly intended to guide biological studies.

Clinical and research classifications

In that connection, there are fundamental differences between a clinical classification and a research classification. First, the aim of a clinical system should be the diagnosis of all disorders, whereas a research system may be constructed on a more restricted basis to fit in with a supposedly “purer,” more homogenous, group of disorders. It will not matter that this means that a substantial proportion of disorders are left out, often those with some different associated psychopathology. Second, in order to ensure that all participants in a study have their disorders diagnosed in the same way, it is now standard practice to specify both the diagnostic instruments to be used and the number of specified features that must be present. By sharp contrast, clinical systems need to start with the *concept* of each disorder, moving on to guidelines on the specific features that should be used to assess the concept. So far as possible, these should include detail on differential diagnosis and differentiation from normality—as well represented in the ICD-11 clinical guidelines. The aim is to ensure that all clinicians apply the guidelines in the same way but without the rigidity inherent in requiring particular instruments to be used and in having strict rules on the number of items required to fulfill the diagnostic requirements.

Of course, it is essential that there is a clear and understandable pathway between clinical and research classifications. Nevertheless, they are sufficiently different for it to be a major problem that the DSM has a classification that is intended to meet *both* research and clinical needs. Most especially, the process to develop proposals for DSM-5 started with a consideration of the number of symptoms required in each symptom domain *before* considering the clinical concept that was to be assessed. The proposals for ICD-11, by contrast, have started with the clinical guidelines before turning attention to the standardized research criteria requirements. Both of us are clinicians and researchers and, therefore, are firmly committed to the needs for both types of classification. However, our strong preference is for the ICD approach that separates classifications for clinical use and for research purposes, with a starting point in the concept and the guidelines for its use.

Biomarkers and neural signatures

Since the seminal article by Robins and Guze (1970) on validation of diagnostic categories, there has been a strong interest in the possibility that there might be the discovery of neural activation patterns or structural differences that could indicate, not only that the patient had a mental disorder, but *which* disorder was present (Gillihan & Parens, 2011). Similar questions have been posed more recently with respect to plans for DSM-5 (Hyman, 2007) and for the ICD-11 (Uher & Rutter, 2012a). This is a new approach; up to now, psychiatric classifications have placed a far greater emphasis on diagnostic reliability than biological meaning or validity (Andreasen, 2007). The hope recently has been that psychiatric disorders might be reconceptualized as disorders of brain circuitry, and that findings from cognitive neuroscience, genetics, and experimental laboratory studies might be brought together for the purpose of classification (Insel *et al.*, 2010). However, it remains unclear if or when this could be realized.

The possibilities have been reviewed in relation to neuroimaging (Gillihan & Parens, 2011) and in relation to a wider range of technologies (Uher & Rutter, 2012a). Similar issues with respect to broader perspectives on biomarkers have also been considered (Rutter, 2014). Much of the research has been conducted with supernormal control groups, without much attention to the need to consider differentiation among diagnostic groups. The lack of good evidence on diagnostic specificity is a problem because neuroimaging technologies may tend to identify general psychopathology rather than individual diagnostic features (Insel & Wang, 2010). In addition, extensive within-group heterogeneity has usually been evident. Genetic findings are similarly inconclusive. There is some meaningful diagnostic specificity but these instances emerge against a background of much nonspecificity (Uher & Rutter, 2012a) and great pleiotropy (Lahey *et al.*, 2011). Thus, copy number variations have been found to be associated with autism, ADHD, schizophrenia and intellectual disability (see Rutter, 2013). The same applies to other identified genetic risk factors.

As has now been widely accepted, there is not yet the evidence required for a scientific classification based on brain findings. Opinions differ on whether technological advances might make it possible in the future. Certainly, it is highly desirable, and probably achievable, for future classifications to be more strongly reflective of scientific knowledge, but the key question is whether this could ever replace clinical classifications. Two slightly different issues need to be considered. First, research strongly suggests that many disorders involve more than one biological pathway (Rutter, 1994, 2006). That need not constitute an obstacle if there is a common endpoint that defines the pathophysiology and that might prove to be the case. But what would be the biological findings in the very common situation of co-occurring disorders? That leads on to the second issue of whether clinical needs could be met by a purely neuroscience classification. Clinicians have to deal with psychopathological

syndromes, and any adequate classification would have to reflect these. Thus, gene-environment interactions ($G \times E$) findings indicate that the neural reflections of $G \times E$ concern processes that are found in individuals without mental disorder (Meyer-Lindenberg & Weinberger, 2006; Hyde *et al.*, 2011). The clinician will nevertheless need to know whether there is a meaningful mental disorder. $G \times E$ findings also suggest that the genetic and the environmental pathways are closely associated. In other words, the fact that a disorder has come about through strong environmental influences does not mean that there will be no brain features. After all, there is good evidence that important environmental effects *are* biologically embedded (Rutter, 2012a). Accordingly, we reject the often-made criticism that a focus on the brain neglects the importance of the environment. The workings of the mind (however brought about) have to be based on what is going on in the brain. The more valid reservation concerns practicalities, given current limited understanding of brain function. Namely, future research is likely to reveal cognitive and emotional processes that have a known biological substrate. Nevertheless, it remains unclear how clinically relevant processes can be reducible to what can be measured with respect to brain structure and function in the individual patient.

Dimensions and categories

DSM leaders have urged that DSM-5 should adopt dimensional approaches insofar as that was possible (Regier *et al.*, 2011). There is little agreement on how that might be accomplished, and many questions remain on how many dimensions, what they should assess, and how they might be measured (see Uher & Rutter, 2012a). Several different reasons have led to the consideration of dimensions. First, internal medicine has long used dimensions alongside categorical diagnoses. Thus, pulmonary physicians measure various dimensions of lung function alongside diagnoses such as chronic bronchitis, emphysema, and chronic obstructive lung disease. Similarly, cardiologists use quantitative measures of exercise tolerance, of blood pressure and of degree of coronary artery obstruction together with diagnoses of coronary artery disease, mitral stenosis and hypertension. Note that the diagnoses have the advantage of giving information about the pathophysiology and dimensions have the advantage of assessing severity. Second, dimensions carry statistical advantages with respect to predictive power (because they make use of differences across the entire range), and avoid the errors associated with cut-offs in the middle of a curve rather than at a natural trough separating two distributions (one of which reflects some disorder). Fergusson and Horwood (1995) clearly showed that this applies in the domain of child psychopathology. Third, there is abundant evidence that many mental syndromes, such as depression, conduct disturbance, and ADHD to give just three examples, function dimensionally. That is to say, the meaning of associations between symptoms

and external factors (such as genetics) applies not just at the extremes but across the full range of symptomatic expression. That has been less obvious in the case of autism and schizophrenia but, even with these supposedly qualitatively distinct disorders, the genetic liability extends well beyond the traditional diagnostic category—as evident in the broader autism phenotype (Le Couteur *et al.*, 1996) and schizotypal disorder (Kendler & Gardner, 1997; Kendler *et al.*, 1998). Whether the liability truly extends across the entire range in the general population is not yet known.

Some might look to statistics to resolve the question of dimensions or categories. Are there two distinct curves or just one? The most famous example of this type of dispute is to be found in the competing claims of Platt and Pickering with respect to hypertension (Swales, 1985). The findings clearly showed the difficulties involved in deciding the number of curves. As Zubin (1967) argued years ago, it makes no sense to argue which is correct because it depends on the purpose for which it is intended. All categories can be dimensionalized, and all dimensions can be made into categories. In the psychopathological arena, the most obvious example is provided by intellectual disability. Mild intellectual disability differs from severe (or profound) disability with respect to life expectancy, fecundity, structural brain pathology, and genetics. As shown here, a categorical distinction works best from a biological perspective. On the other hand, if the need is to predict later educational attainments or social functioning, IQ is best used as a continuous dimension.

In relation to clinical usage, categorical distinctions are unavoidable. There have to be decisions on whether or not to use medication, to admit the child to hospital, or take him/her into care. It would make no sense, for example, to vary the dose of antidepressant according to the score of some depression scale. Considerations such as these make it inadvisable to change the whole of classification from categories to dimensions. On the other hand, we see great value in including some dimensions in a mainly categorical classification. Thus, the multi-axial version of ICD-10 for use by child psychiatrists (World Health Organization, 1992) was well accepted and worked very well with dimensions for IQ, and for overall social functioning, for example.

Accordingly, we deplore the bureaucratic decision of WHO that ICD-11 cannot have any dimensions. That is a fundamentally absurd requirement. Thus, with respect to autism spectrum disorders, clinicians need to know the level of language and of intellectual functioning. Neither changes the diagnosis, but they are important for prognostic purposes. Perhaps, the way forward with respect to ICD-11, as with ICD-10, is to have a multi-axial version published by the Mental Health Division rather than WHO itself. In other words, we strongly urge a pragmatic, problem-solving approach.

In that connection, it is important to note that classification has to encompass associated somatic conditions and associated psychosocial circumstances as well as mental disorders. Both are available in the ICD but are *not* provided in the DSM. Nevertheless, there must be a sensible walkway between ICD-11

and DSM-5, however both are organized. Thus, for example, in ICD-11, Rett syndrome will presumably be coded in the neurology section rather than the psychopathology one. The same will probably apply to some sleep disorders (such as narcolepsy).

The supposed separateness of syndromes

Traditionally, diagnoses were conceptualized as syndromes or disorders that were truly distinct and separate from one another. The implication was that mixed or overlapping patterns should be the exception rather than the rule. Ordinarily, there should be, in effect, clear water between diagnostic categories. Clinical and research decision-making would be greatly simplified if this truly were the case, but it is not. Much research has shown, for example, that phenotypic overlap between autism and ADHD is common and that the two disorders (and others) partially show the same genetic liability (Rutter, 2014). Similar issues apply to the connection between bipolar disorder and schizophrenia (Craddock & Owen, 2010). The overlap among diagnoses clearly poses major problems for any classification system; the issues are discussed in Chapter 3. Nevertheless, none of this should be taken to mean that there are no meaningful differences among syndromes. We use, below, a range of possible validating criteria to determine the extent to which there are such differences, but, because of the overlap among syndromes, it cannot be expected that all the criteria will point in the same direction.

Validation of diagnostic categories

For diagnoses to be scientifically meaningful and clinically useful, it is necessary that the diagnostic distinctions be validated. As realized a long time ago (Robins & Guze, 1970; Cantwell, 1975; Rutter, 1978), such validation must be on the basis of criteria that are *external* to the defining signs and symptoms. Such criteria may derive from quite varied sources—such as age and sex trends, response to different forms of treatment, long-term outcome, genetic influences, and psychosocial influences. The expectation cannot be that all of these will validate the diagnosis, but confidence in the validation will increase with the number of sources that show that the diagnostic distinctions hold up. As already noted, a major problem lies in the evidence that diagnoses are not as distinct and separate as was traditionally supposed. However, our initial discussion of validation will be based on what has been found with existing diagnoses. The review here is selective, but it provides guidance on the extent to which there is validating evidence on some of the main diagnoses.

Age trends and sex differences

Age differences were used in the 1960s and 1970s to separate autism and schizophrenia (Rutter, 1972). Up to that time period,

autism had been termed an infantile psychosis and had been regarded as an early manifestation of schizophrenia. However, the data from research by both Kolvin (1971) and Makita (1966) showed that psychoses tended to be either infantile in their first manifestations (suggesting autism) or adolescent in onset (suggesting schizophrenia), with rather few onsets in the intervening years. On this basis, there did not seem to be continuity between autism and schizophrenia. Autism also showed a marked male preponderance (3 or 4 to 1) whereas schizophrenia differed much less in sex ratio.

Later research showed that an onset particularly concentrated in the preschool years picked out a group of disorders, like autism, that involved neurodevelopmental impairment and which were more common in males than females. Thus, this applied to attention deficit hyperactivity disorder (ADHD) (Gershon & Gershon, 2002), dyslexia (Miles *et al.*, 1998), specific language impairment (Bellani *et al.*, 2011), and anti-social behavior with a childhood onset (Moffitt *et al.*, 2001). The disorders where prevalence peaks in adolescence, such as depression and eating disorders, were strikingly different in showing a female preponderance and no particular association with neurodevelopmental impairment (Rutter *et al.*, 2003).

Note that age of onset as such is not as clear a differentiator as might be supposed. Findings from the Dunedin longitudinal study showed that a *majority* of mental disorders requiring treatment in early adult life had already been manifest in childhood or early adolescence (Kim-Cohen *et al.*, 2003; Merikangas *et al.*, 2010). These findings, however, concern first manifestations in the childhood years and *not* onset in infancy.

Familiality and genetics

There is good evidence that autism spectrum disorders (ASD) are associated with a markedly increased family loading for ASD and a somewhat wider range of social and communicative impairments (Rutter & Thapar, 2014). Moreover, twin data indicate that the genetic liability applies across this range (Le Couteur *et al.*, 1996). There is possibly some increase in anxiety disorders but no loading for schizophrenia. Conversely, schizophrenia spectrum disorders (SSD) are associated with an increased familial loading for SSD (including schizotypal disorder) but not for ASD. SSD and bipolar disorder (BD) have a somewhat different set of genetic risk factors, but there is more overlap between SSD and BD than appreciated in the past (Moskvina *et al.*, 2008).

Depressive disorders generally are associated with both an increased familial loading for depressive disorders and with a moderate heritability (Levinson, 2006). However, twin data indicate that there is a strongly shared genetic liability between depression and generalized anxiety disorder (Kendler & Prescott, 2006). The overlap, however, is much less for depression and specific phobic disorders (Franić *et al.*, 2010). Bipolar disorders are associated with an increased family loading for unipolar depressive disorders, but the converse is much less

common (McGuffin *et al.*, 2003). That is to say, only a small proportion of the relatives of individuals with a unipolar disorder have a bipolar disorder. The implication would seem to be that the two are meaningfully different. Nevertheless, some relatives of patients with BD will have depression without mania because manic/hypomanic episodes have yet to occur.

Genetic studies indicate some shared genetic liability between obsessive-compulsive disorder (OCD) and tic disorders, including Tourette's syndrome and chronic multiple tics (Leckman *et al.*, 2002). However, there may also be some shared genetic liability between OCD and anxiety disorders (Bolton *et al.*, 2007). There is also good evidence on both the familiarity of conduct/dissocial disorder and the fact that to an important extent this reflects genetic influences (Moffitt, 2005). This seems to differ from the findings on emotional disturbance, but there has been rather little study of the possible shared genetic liability between conduct/dissocial disorder and emotional disturbance. Twin and family studies both show the importance of genetic influences on eating disorders that differ from those on other disorders, but the evidence is more contradictory on possible differences between anorexia and bulimia nervosa.

The clearest genetic validation concerns Rett syndrome in which a gene on the X chromosome with a mutation that affects the methyl-CpG-binding protein (MeCP2) is responsible for the disease—this not being found in other autism spectrum disorders.

The subclassification of intellectual disability into severe/profound and mild also has genetic validation in that the former is associated with multiple major genetic mutations (such as that responsible for Down syndrome) whereas that is very much less common in the case of mild intellectual disability. Also, whereas mild disability shares genetic liability with the general population, severe intellectual disability does not.

Both molecular and behavioral genetic findings (Kendler *et al.*, 2003) have shown that misuse of various psychoactive substances share much the same genetic liability. That is, there is very little indication that the misuse of different drugs is associated with different genes.

Within conduct/dissocial disorders, childhood onset is more strongly associated with alcohol/drug problems in one or both parents than it is in adolescent onset (Silberg *et al.*, 2014).

Psychosocial correlates

For the most part, major psychosocial risk factors do not show diagnostic specificity (McMahon *et al.*, 2003) although there is some evidence that this, at least in part, is a consequence of the extensive co-occurrence of disorders (Shanahan *et al.*, 2008). There is some tendency for severe discord and conflict to be particularly associated with conduct disorders (Shanahan *et al.*, 2008) but it also constitutes some risk for other disorders.

The two disorders showing a moderately strong specific association with certain psychosocial features are what used to be called post-traumatic stress disorder (PTSD) and disinhibited

attachment (now social regulation) disorder. PTSD in DSM-IV and ICD-10 was described as a syndrome usually arising soon after some exceptional traumatic event that involved actual or threatened death or serious injury and which included recurrent intrusive recollections of the event, persistent avoidance of stimuli associated with the trauma and increased arousal and hypervigilance. Unfortunately, reports of PTSD have often included a wider range of stress events, and the symptomatology has included rather general features such as irritability and difficulty sleeping. The ICD-11 proposals have argued for four slight but important modifications in order to emphasize the specificity of the disorder. First, a requirement of onset soon after the event (thus eliminating much delayed onset in which the causal connection is less easy to establish); second, a tight restriction to physically threatening or dangerous events; third, an elimination from the diagnostic criteria of features of irritability and insomnia which apply to many forms of mental disorder; and, fourth, a renaming to “hyperarousal/hypervigilance syndrome” in order to avoid its inclusion in a broader range of nonspecific stress related disorders. It is not that the syndrome does not include anxiety or depressive features. To the contrary, they are common, but they are not indicative of the specificity of the syndrome.

The second situation-specific disorder is the “disinhibited social regulation disorder” (previously termed as reactive attachment disorder). Zeanah and Gleason (2011) rightly argued that this should not be classed as an attachment disorder because it was shown by the style of interactions with *strangers* and not by the child's response to separation from and reunion with a caregiver. The syndrome is strongly associated with an early upbringing in profoundly depriving institutions (it is not yet known whether, or how often, it arises following profound deprivation in a family setting or an institutional upbringing that is not globally depriving). Both this syndrome and the “hyperarousal/hypervigilance” syndrome are distinctive in persisting after the risk situation is no longer present.

A third example of a psychosocial validating feature concerns schizophrenia. It differs markedly from the first two examples in that there is no suggestion that schizophrenia usually has a psychosocial origin. Nevertheless, schizophrenia is distinctive by virtue of its association with a prolonged upbringing in an urban environment during the childhood/adolescent years, but apparently not with living in an urban environment only *after* the childhood/adolescent years (see Pedersen & Mortensen, 2001; van Os *et al.*, 2010; Vassos *et al.*, 2012). Schizophrenia is also associated with migration from a developing to a developed country (McGrath *et al.*, 2004; Cantor-Graae & Selten, 2005; Jones & Fung, 2005). Apparently, the risk effect is associated with living in an area in which most of the population does not share the same ethnicity. Some of the key studies have involved migrants from the West Indies to either the UK or Netherlands in which the risk of schizophrenia has been found to exceed that in the island from which they migrated and that in indigenous whites in the countries to which they migrated. Although the

main association is with schizophrenia it also applies to a lesser extent to other psychoses.

Whereas mild intellectual disability is much more common in children reared in poverty and social disadvantage, this is not the case with severe intellectual disability.

Poverty is associated with antisocial behavior but not with emotional disturbance to anything like the same extent (see Costello *et al.*, 2003).

Long-term course

Rett syndrome stands out with respect to the downhill course associated with neurological impairment and/or epilepsy. This is not found with any other form of psychopathology in childhood (Neul, 2011). However, autism is also distinctive in terms of the development of epileptic attacks in adolescence/early adult life (Bolton *et al.*, 2011) and with an apparent loss of skills in a minority of individuals, usually associated with both a worsening in behavior and often with epilepsy (which might begin before or after the cognitive loss (Howlin *et al.*, 2014).

Antisocial behavior in adult life is almost always preceded by conduct disorder (CD) in childhood (Robins, 1966, 1978). However, only about two fifths of cases of CD persist into adult life. In DSM-IV and ICD-10, CD was treated as a mental disorder, but antisocial behavior in adult life was treated as a personality disorder, placed on a different axis. In both DSM-5 and ICD-11, the two will be brought together as the same disorder. This is well justified, but it raises the consideration of how to recognize (and code) childhood onset CD/dissocial behavior that does *not* persist into adult life. At the time of writing, no satisfactory empirical solution has been found.

Long-term follow-up studies of patients who suffered from a depressive disorder in childhood have clearly shown a very high rate of recurrence in adult life, associated also with a much increased risk for suicide and attempted suicide (Fombonne *et al.*, 2001a, b). This recurrence rate is relatively specific to depressive and anxiety disorders, unless the depression in childhood is associated with a conduct disorder, in which case the outcome includes a much broader range of psychopathology and of social dysfunction. The risk for suicide is also higher in the group with depression and CD in childhood reflecting the fact that CD, as well as depression, constitutes a risk factor for suicide. The evidence on the frequency of bipolar disorder in adult life is more contradictory. Harrington *et al.* (1990), Fombonne *et al.* (2001a), and Weissman *et al.* (1999) all found that transition from a unipolar depressive episode in childhood to a bipolar disorder in adulthood was quite uncommon, whereas a few others (e.g. Geller *et al.*, 1994) have found it to occur more frequently. Finally, from a classification perspective, it is important to note that the recurrence of further depressive disorders is as high in the case of both dysthymia and minor depression as it is with major depressive disorders (Angst, 2009).

Schizophrenia usually has a profound negative impact on personal development and functioning (Jablensky, 2009). Nevertheless, in about a third of cases, a relatively benign

outcome is seen, and yet other cases run an episodic course. The outcome tends to be worse for schizophrenia beginning in childhood, with an insidious onset and much negative symptomatology (Hollis, 2008). About a quarter of patients with schizophrenia followed for many years develop a major depressive disorder. The converse, however, does not apply; only a very small proportion of patients with major depression develop schizophrenic features during a long-term follow-up. Thus, mood disturbances may be considered part of the schizophrenic spectrum, but schizophrenic disturbances are not part of the depression spectrum.

Obsessive-compulsive disorders (OCD) show a strong tendency to persist into adult life but there is waxing and waning of the symptoms, often with associated anxiety and/or depression (Flament & Robaey, 2009). Many cases of OCD also have tics and there is an association with Tourette's syndrome in some cases.

ADHD shows a substantial degree of persistence into adult life (Taylor & Sonuga-Barke, 2008), but the pattern of manifestation changes with increasing age—hyperactivity becomes less frequent, and inattention becomes more prominent (Larsson *et al.*, 2011). In addition, ADHD predisposes to development of conduct disorder. This predisposition is already evident in childhood but, even in cases without CD in childhood, ADHD in early life is associated with an increased risk of antisocial behavior when older (Mannuzza *et al.*, 1998).

CD with an onset in childhood has a substantially greater likelihood of persisting into adult life than CD beginning in adolescence (Silberg *et al.*, 2014).

About half the cases of speech delay that are diagnosable at 4 years of age resolve with little in the way of sequelae but those that do not are followed by a much increased rate of reading disorders, and some increase in emotional and behavioral problems (Rutter, 2008). In cases with a more severe disorder of receptive language, there is also a marked increase in problems in love relationships.

Disinhibited social regulation disorder has been shown to persist long after removal from the depriving circumstances that led to its origin (Bruce *et al.*, 2010; Zeanah & Gleason, 2011), whereas reactive attachment disorder usually remits following a change of circumstances.

Drug response

Given the current views on biological factors in the etiology of mental disorders, it might be supposed that drug responses should be useful in the validation of diagnostic categories. In practice, this has not proved to be the case—primarily because so few drugs have single actions, but also because there are marked individual variations in response to all forms of medication. Thus, prior to Rapoport *et al.*'s (1980) definitive research findings, it was commonly supposed that stimulants had a paradoxical effect in ADHD. She found that, contrary to that supposition, stimulants had much the same qualitative effect of improving attention in everyone. A good response to stimulants

in no way validates the diagnosis, and a lack of response does not invalidate it. In adults, tricyclic antidepressants have been widely, and effectively, used in the treatment of depression. However, they have also been shown to bring benefits to individuals with wetting or with ADHD—presumably through different mechanisms. The response of individuals with depression to tricyclic medication does differ, however, between childhood and adult life. In children, unlike in adults, tricyclics bring no benefits for depression (Hazell *et al.*, 1995), whereas selective serotonin reuptake inhibitors (SSRIs) are effective in children (Emslie *et al.*, 2004, March *et al.*, 2004) as well as in adults. This might suggest that depression in childhood/adolescence is different from that in adults, but this would not be supported by other validating criteria.

The nearest approach to a drug response that is diagnostically specific is provided by the use of lithium as an effective prophylactic against the recurrence of bipolar disorder (Tondo *et al.*, 2001; Geddes *et al.*, 2004). However, although not much used in the same way for unipolar depression, there is evidence that it, too, is similarly responsive to lithium (Souza & Goodwin, 1991). In addition, lithium may have useful effects in the treatment of aggressive behavior (Craft *et al.*, 1987; Tyrer, 1994; Einfeld, 2001) and of schizo-affective disorder (Jefferson, 1990). The evidence on these other uses of lithium is much thinner than on its use in the prevention of relapses in bipolar disorder, but a beneficial response to lithium does not validate the diagnosis of bipolar disorder. Thus, even for the strongest potential examples, the data on validation based on therapeutic response do not strongly distinguish specific disorders or even groups of disorders.

The topic may also be considered from the other end. Thus, are there meaningfully different responses to medication in different disorders? The key finding here is that autism is highly unusual in there being little or no effect on core symptoms from any form of medication (Buitelaar, 2003). The implication seems to be that this defines autism as a unique condition. This could mean that it may not involve dysfunction in any of the main neurotransmitter systems. Alternatively, this could mean that any such dysfunction is so fundamental or early-appearing that it remains impervious to current pharmacological approaches.

Cognitive impairments and developmental delay

Beyond the unique response to medications, autism also is distinctive with respect to its associated cognitive profile. Here the disorder exhibits both specific social cognitive features, such as impaired theory of mind and weak central coherence (Frith, 1989; Happé, 1994) and general intellectual disability (Bock & Goode, 2004), as well as unusual talents and savant skills (Happé & Frith, 2010). There is no other diagnosis with this particular pattern of cognitive strengths, limitations, and differences. Baron-Cohen (2002) sought to integrate findings by arguing that autism is associated with high systemizing skills, as well as poor empathizing (Baron-Cohen, 2011). Research by others has raised queries about Baron-Cohen's theory (Morsanyi *et al.*,

2012) and, at least so far, it is not contributory with respect to diagnostic validity.

ADHD has a weaker association with cognitive impairments (as compared with that found with autism), but, at a group level, it is associated with an IQ slightly below 100 and with a variety of executive planning and other deficits (Rutter *et al.*, 1998; Taylor & Sonuga-Barke, 2008; Frick & Nigg, 2012).

Dyslexia is associated with phonological and other related deficits evident in the preschool period (Lyytinen *et al.*, 2006; Snowling & Hulme, 2008). This would seem to be diagnostically distinctive but it has not been studied systematically in other diagnoses.

Schizophrenia is often preceded by mild language and motor impairments in the preschool years and by an IQ below 100 at all ages (Cannon *et al.*, 2002). These associations are not found in anxiety and depressive disorders and are much less evident in bipolar disorders. Thus, there is a substantial degree of diagnostic specificity. On the other hand, the impairments do not follow a recognizable pattern and, therefore, cannot be diagnostically useful at an individual level.

Childhood onset conduct/dissocial disorder is distinctive in its frequent persistence into adult life and lifecourse-persistent antisocial behavior is distinctive in its association with hyperactivity/impulsivity and developmental impairments (Moffitt *et al.*, 2001).

Children with a range of developmental disorders show an increased rate of tics. Thus, Kurlan *et al.* (2001) reported an increase in the prevalence of tic disorders in children in special educational settings. Conversely, children with tics tend to show deficits in visual-motor integration (Schultz *et al.*, 1998; Bloch *et al.*, 2006).

Biology

Severe/profound intellectual disability is the disorder with much the most distinctive biological features (Simonoff *et al.*, 1996). It is associated with a much reduced fecundity, gross neuropathological abnormalities, and with clinical brain disorders (such as cerebral palsy or epilepsy). None of these apply to mild intellectual disability.

Autism is associated with an increased rate of epilepsy (about 20–25%) as compared with the general population, but this does not differ from that found in intellectual disability. However, it does differ with respect to the age of onset of seizures being particularly in adolescence or early adult life (Volkmar & Nelson, 1990; Bolton *et al.*, 2011). Autism is also associated with an increased head size in the preschool years whereas intellectual disability is more often associated with a reduced head size (Woodhouse *et al.*, 1996; Fombonne *et al.*, 2001a).

There is much evidence that other mental disorders are associated with structural and functional brain imaging findings but, whereas these differentiate from normal, there is little or no evidence of diagnostic specificity. Accordingly, they provide little evidence on diagnostic validity. It seems curious to have so few examples of biology providing diagnostic validation. After all,

there has been a huge increase in both the quantity and quality of neuroscience (Charney & Nestler, 2011), and this has given rise to many leads on possible biological validators. As already noted, however, most of the research has not included systematic comparisons of different diagnoses.

Validating criteria

Table 2.1 summarizes the findings on the extent to which seven possible criteria support distinctions among diagnostic categories. Three main points need to be made on the findings. First, some of the criteria do not necessarily reflect biological validation. Thus, this is clearly the case with epidemiological findings on age trends/sex differences and the findings on a long-term course. Nevertheless, they are included because they provide data that are likely to have important clinical implications. Second, the research has mainly focussed on categorical distinctions and hence less is known on the validity of the dimensions that have been shown to apply to many multifactorial mental

disorders. Third, the research has largely ignored the evidence on the frequently extensive overlap among diagnoses (as noted earlier in this chapter).

Nevertheless, despite these important limitations, there is quite extensive evidence on validating criteria and, as summarized in Table 2.2, these lead to reasonably robust conclusions. First, there are some nine diagnoses for which there is validating evidence of several different kinds and another half dozen for which there is some validating evidence from at least two different criteria. Second, there are at least half a dozen diagnostic categories for which the evidence suggests a lack of validity. This applies to the subcategorization of personality disorders, of anxiety disorders, of substance abuse disorders, of schizophrenia and of the differences between major depressive disorder and dysthymia, of the diagnosis of adjustment disorder, and of the grouping of nonspecific stress disorders. This lack of validating evidence does not necessarily mean that the diagnoses should be dropped from ICD-11 or DSM-5, but it does mean that the

Table 2.1 Possible validating criteria for different disorders.

	Epidemiology	Familiality	Psychosocial	Drug response	Cognitive impairment	Biology	Long term course
Autism	X	X		X	X	X	X

Table 2.2 Level of validating evidence for a range of disorders.

Relatively well validated	Some validating evidence	Some evidence suggesting lack of validity
Autism	Disinhibited social regulation	Adjustment disorder
Schizophrenia	Antisocial childhood onset	Subcategories of personality disorder
ADHD	Bipolar disorder	Subcategories of anxiety disorder
Dyslexia	Substance abuse	Differences among substance abuse disorders
Anxiety/depression	Conduct/dissocial disorder	Difference between major depressive disorder and dysthymia
Severe intellectual disability	Early disorders	Subcategories of schizophrenia
Rett		The grouping of non-specific stress disorders
OCD/tourette's		
SLI		

onus has to be placed on those who argue for their retention to demonstrate their utility for either clinical work or research. We return to this question when discussing the changes envisaged for DSM-5 and ICD-11.

“Lumping” or “splitting”

Passionate arguments have often been put in favor of “lumping” diagnoses into broader groupings or “splitting” them up according to many finer distinctions. There can be no single “right” answer on this because all depends on both the purpose of the classification and the type of disorders being considered. Thus, unlike DSM, ICD classifies all medical conditions. These include a large number of infectious and parasitic diseases. Although these share a range of common features, from both biological (scientific) perspectives and clinical usage, there must be much splitting to cover both the specific causative agent and the body organ affected. That does not apply to the multifactorial disorders that constitute most of mental disorders.

However, classifications of psychopathology have usually involved three different levels, and this applies to both ICD-11 and DSM-5. It is often assumed that validation data are strongest at the first broadest level, becoming progressively weaker with increasingly narrow levels. Nevertheless, this assumption is not correct. The first level concerns broad groupings of diagnoses—such as mood disorders and schizophrenia spectrum disorders. In ICD-10 and DSM-IV, these were constrained by the requirement to have only 10 groupings, and some of the clusters were very arbitrary in what they included and excluded. One of the best decisions of WHO, backed by the APA, was to allow more than 10 clusters, and to expect that, so far as possible, these should involve conceptual coherence. This led to the removal of a cluster of childhood onset disorders in view of the evidence that many disorders that largely manifest in adult life (such as schizophrenia) actually show their first manifestations in childhood. It also meant that conduct disorders and antisocial personal disorders were brought together into the same cluster. It has to be accepted that some clusters are less well validated than others. Thus, there are good reasons for having a cluster for obsessive-compulsive and other related disorders, but the evidence that body dysmorphic disorder should be included is less than desirable (Phillips *et al.*, 2010). Similarly, there were practical reasons for combining feeding disorders (such as pica) and eating disorders (such as anorexia nervosa) in the same cluster, despite the paucity of supporting validating evidence (Uher & Rutter, 2012b). Similarly, the grouping together of all elimination disorders is tidy but not well validated. It is evident that the breadth of grouping is not a good index of validity.

The second level is provided by the various specific diagnoses within each cluster. For example, the new cluster of neurodevelopmental disorders has, very reasonably, specific diagnoses for autism spectrum disorders and ADHD. As noted above, some of these are better validated than others. However, the

key concern over the separateness of diagnoses undermines the validity claim. For example, it is clear that both at the phenotypic level and causal influences level there is substantial overlap between ADHD and autism—with the reasons for it still obscure (Rutter, 2013).

The third level is provided by the subcategorization within specific diagnoses. For example, there is a cluster for “disruptive behavior disorders” and, within this cluster, there are separate diagnostic categories for oppositional/defiant disorder (ODD), conduct/dissocial disorder (CDD) and intermittent explosive disorder. At the third level, CDD is subdivided into those with a childhood onset and those in which the onset is in adolescence or adult life. As discussed above, in this case the subcategorization has some supporting validating evidence. The same applies to separation of social regulation disorder from reactive attachment disorder, as well as the split between severe and mild intellectual disability, and the separation of Rett syndrome from the rest of autism spectrum disorders. Some narrow diagnoses do have validating evidence. In other cases, the evidence is largely lacking (see Table 2.2).

In our view, this three level organizational structure provides a good approach and sets a sound agenda for future refinements but questions remain with respect to both the clusters and the individual diagnoses. Perhaps the greatest uncertainties concern the subcategorization. The fields of substance abuse and of personality disorders provide interesting examples of some of the issues at stake. In ICD-10, there is an overall, very large, cluster of mental and behavioral disorders due to psychoactive substance use. That seems appropriate in view of the public health importance of the disorders and the evidence of biological dysfunction. But why does the cluster not include abuse of other substances (such as steroids or antidepressants, which were placed in F55—a quite separate cluster) and why did it not include behavioral addictions (such as pathological gambling, which was coded as habit/impulse disorder, or internet addiction)? Why is the primary coding based on the drug used, rather than the disorder symptom pattern? Clearly, these questions have been asked by others and it appears that the lack of consensus probably reflects both the rigidity of the APA rules and the ideology and the apparent vested interests of some people in the field. In our view, there needs to be a total rethink on how best to deal with this grouping of disorders. It is essential that this is driven by empirical evidence. Hopefully, too, this should lead to a major reduction in the total number of disorders in this cluster.

The field of personality disorder is similar with respect to the need for some such grouping (because of its clinical importance) but it differs in the type of problems. First, there is such a huge frequency of co-occurrence of different personality disorders that it is quite uncommon for only one to be diagnosed. Second, there is a weak evidential basis for many of the separate diagnoses. Third, the approaches in DSM-IV and ICD-10 are rather different with the former using theoretical concepts (such as borderline personality disorder) and the latter

mainly using trait features (such as anxious or paranoid). Once again, a total rethink is needed, focussing on empirical research findings—hopefully with a bringing together of the DSM and ICD approaches.

With respect to the overall issue of “lumping” or “splitting,” the answer should be to have as many subdivisions as required for either clinical utility or scientific validity, but no more than is needed. In other words, the aim is to have as few subdivisions as essential for the purposes to which the classification is used, but that will vary according to the purpose intended. To take an obvious example, the classification for primary care use will have to have far fewer diagnoses than those used in tertiary care settings because detailed subdivisions will require more data than can be obtained in a brief primary care consultation.

Threshold for diagnosis

There are two rather separate issues with respect to thresholds. First, there is the question of whether or not impaired social functioning should be required. It was in DSM-IV but in ICD-10 it was not. Rather, impairment was coded separately, and the same is likely to apply in DSM-5 and ICD-11. The DSM justification is that certain diagnoses are much too frequent if impairment is not required; the most striking example is provided by phobias. The solution, however, should lie in the specifications for anxiety disorders rather than any overall rule. The ICD justification is that there needs to be a way of recognizing disorders that are well controlled through medication (or other means). Thus, schizophrenia does not cease to exist just because symptoms are well controlled through appropriate psychotropic medication. The parallel might be with well-controlled diabetes. Of course, this is more straightforward if there is some physiological (or other biological) test for the disorder. This would become easier in the field of psychopathology if biomarkers were able to live up to their potential (Rutter, 2014).

The second issue concerns how to deal with sub-syndromal patterns such as the broader autism phenotype and so-called prodromal schizophrenia. There is good evidence that such patterns are reasonably common, that they involve a substantial risk for the development of the traditional syndrome (i.e. autism and schizophrenia in the examples given), and that services are needed to provide interventions and reduce the risk for progression to the traditional syndrome. However, it would not be appropriate to have a diagnosis on the basis of the risk for some mental disorder in the future, particularly since only some are likely to progress to develop the traditional syndrome and by no means all warrant service provision. In our view, it is desirable to include diagnoses for these patterns provided that the criteria are explicit with respect to the severity required and provided the diagnosis is labeled as needing further testing. The latter requirement will be possible in ICD-11 but not in DSM-5 (because disorders needing testing are placed only in an appendix). It needs also to be recognized that there are possible

dangers in such syndromal diagnoses if the interventions used involve serious side-effects (as would be the case with some psychotropic medications). There may also be concerns that pharmaceutical companies will see the opportunity for new marketing that targets those who may not need treatment. It should be added that autism and schizophrenia are by no means the only examples. Closely similar issues apply in the fields of depression and of eating disorders, to which we would apply the same approach—that is, a firm requirement of adequate severity and a clear differentiation of risk profiles from profiles associated with manifest pathology.

For some critics, the provision of new diagnoses implies the medicalization of social problems. ADHD has often been targeted on this basis. However, this is wrong-headed on several different grounds. First, classifications are not restricted to medical diseases. Second, there is abundant evidence that ADHD and even some sub-syndromal problems are accompanied by major suffering that can be alleviated (at least in part) by appropriate treatment. Third, most psychiatric diagnoses are multifactorial and involve psychosocial causal influences to a varying extent. Fourth, there are strong reasons for including diagnoses that are predominantly precipitated by social experiences (as would be the case, for example, with what used to be called PTSD). Fifth, there is substantial evidence showing the biological embedding of psychosocial experiences (Rutter, 2012a).

Separate classifications in different countries

Some countries have wanted to have their own classifications rather than use either DSM or ICD. That would seem to jeopardize the main value of classification for communication among clinicians and researchers. On the other hand, it may be desirable for slight modifications of universal classifications in order to adapt them to fit in with local methods of working. However, when this is done, it is also essential to provide an explicit walkway between the classifications. There might also be a need for a separate classification to deal with supposedly culture-specific syndromes. However, these seem to be decidedly rare and the need is better met by appendices in universal classifications to indicate how to deal with the issue (as was the case in DSM-IV).

Staging or severity of disorders

Throughout medicine it is very common for dimensions to be used to specify either the staging of a disorder or its severity (see, e.g. such usage in the fields of cancer, cardiology and pulmonary medicine). In relation to childhood psychopathology, severity dimensions have been proposed for both language level and intellectual level in the diagnosis of autism spectrum disorders; there are also other examples. We see this as an important and clinically useful application of specifiers and it makes no

sense that WHO has issued an edict that dimensions cannot be introduced into ICD-11.

DSM-5 and ICD-11

At the time of writing, while DSM-5 has been published, it will not be known for several years what ICD-11 will look like. Nevertheless, it is appropriate for us to comment on both the process of dealing with the revised classifications and some of the specifics. Regarding the process, it was foolish to prevent any scrutiny or critique of the existing classifications. As one of us has noted (Rutter & Uher, 2012; Rutter, 2012b, c), there are major problems with both ICD-10 and DSM-IV. For example, many diagnoses have rarely, if ever, been used and there are ridiculously high rates of co-occurrence. The way forward ought to have been to consider which inadequacies in the existing classifications required some kind of remedial action—but that is precisely what was forbidden. Second, well after the working groups were established, the APA set up a special committee to examine the scientific validity of new proposals. This was flawed from the start. If diagnoses were not included in DSM-IV in the new form, in most cases validity data were unlikely to be available. In addition, there was the further problem that the special committee was allowed only to comment on the specific working group proposals submitted, which often came piecemeal, preventing any assessment of the diagnostic proposals as a whole. Third, new diagnoses proposed for DSM-5 that required further testing had to be placed outside the main classification in an appendix that effectively prevented their use and, hence, their testing. Fourth, validity was seen as an essential deciding criterion without reference to either clinical usage or public health considerations (although these were added late in the process). Fifth, the DSM field trials were undertaken at a time that *preceded* decision on the diagnoses to be tested. Finally, harmonization between ICD and DSM was not treated as a priority (other than with respect to an early meeting on the clusters to be used).

Despite these serious reservations about the process, we need to go on to ask whether, nevertheless, DSM-5 and ICD-11 will be better than what existed before. The extension of the number of clusters available was certainly a really valuable change. It is also likely that a few anomalies will be corrected. However, at the time of writing, there is little evidence that the problems we have noted will have been dealt with; the number of diagnoses will similarly remain ridiculously large; and extensive co-occurrence of diagnoses will continue. We regret the lack of harmonization between DSM-5 and ICD-11.

As we have tried to explain in this chapter, for all its difficulties, classification is tremendously important, not just to enable effective communication, but because diagnoses constitute a passport to services and shape research approaches. Because both of us have been engaged in ICD-11 and DSM-5 discussions in the past, we have to share the guilt in not succeeding in doing more to make things better. The preparation for classification revisions provided a golden opportunity to move forward in an important

way. We regret, therefore, that, with a few important exceptions, that opportunity was not seized and acted upon.

CHAPTER 3

Neurodevelopmental disorders

Anita Thapar¹ and Michael Rutter²

¹Child and Adolescent Psychiatry Section, Institute of Psychological Medicine and Clinical Neurosciences, Cardiff University School of Medicine, Cardiff University, UK

²Social, Genetic and Developmental Psychiatry (SGDP) Research Centre, Institute of Psychiatry, Psychology and Neuroscience, King's College London, UK

In this chapter we begin by considering what disorders have been classified as neurodevelopmental and why. In DSM-5 and (probably) the forthcoming ICD-11, specific learning disorders (involving reading, writing, and arithmetic), motor disorders, communication disorders, autism spectrum disorder (ASD), attention deficit/hyperactivity disorder (ADHD), intellectual disability (ID) and tic disorders are all placed in a neurodevelopmental cluster. We consider the rationale and discuss both the concept of comorbidity and the hypothesis of “maturational” lag. Detailed descriptions of specific disorders and appropriate interventions are covered in the disorder chapters of this book.

Neurodevelopmental disorders (which show a frequent co-occurrence) can be considered to involve impaired development of cognitive or motor functions manifest from childhood that have a steady course without marked remissions or relapses, but tend to lessen with increasing age. Neurodevelopmental disorders may also involve aberrant functioning. Neurodevelopmental disorders, whilst defined as categories for clinical purposes, can also be viewed as quantitative dimensions (see Chapter 2).

The classification of neurodevelopmental disorders

As discussed by Rutter and Pine in Chapter 2, it is usual in diagnostic classification systems to have several levels of information, and both ICD-11 and DSM-5 are no exception to that. However, there is one very important difference between new classifications and the old. The decision that the overall number of diagnostic groupings or clusters need *not* be restricted to ten means it has been possible to have a more logical conceptualization of each cluster. It is in that spirit that we review the issues and findings with respect to neurodevelopmental disorders.

Rispens *et al.* (1998) have provided a useful historical overview of how neurodevelopmental disorders have been dealt with in classification systems. It was noted that the concept of specific developmental disorders was first used as a generic term that denoted delays in a broad variety of areas of development but that later, disorders such as hyperactivity, enuresis and tics were excluded, with specific developmental disorders being used as a higher order concept uniting impairments in the domains of language, scholastic skills and motor coordination. This group of specific neurodevelopmental disorders was initially put on a separate axis (although that is not the case now) on the grounds that they differed from the general run of psychopathological conditions in three key respects: (1) an onset that is invariably during infancy or childhood; (2) an impairment or delay in the development of functions that are strongly related to biological maturation of the central nervous system; and (3) a steady course that does not involve the remissions and the relapses that tend to be characteristic of many mental disorders. In keeping with these criteria, impairments in most neurodevelopmental disorders tend to lessen as the children grow older, although deficits often continue into adult life.

Harris (1995) has conceptualized neurodevelopmental disorders differently to include single gene disorders such as the Prader–Willi syndrome or disorders deriving from prenatal insults or toxins such as the fetal alcohol syndrome. At first sight, it might be thought that they have much in common with the narrower concept because they usually have neural impairment, involve cognitive deficits of various kinds and are characterized by a steady course without remissions or relapses. However, a grouping based on such a mixed bag of genetic and environmental causes does not seem to be helpful. Accordingly, we have excluded conditions that are not multifactorial in origin because there is a separate category for them in ICD-11 if the distinctive behavioral pattern is *wholly* due to a medical

condition classified elsewhere (usually this would be in the neurology section).

In addition to disorders of language, scholastic skills and motor function, the neurodevelopmental cluster in DSM-5 and ICD-11 now includes ID. Intellectual Disability had not been included in earlier concepts because of the importance placed on functioning that was discrepant with mental age. That has not proved a useful approach and therefore it is entirely reasonable to include ID in this cluster. The cluster also includes ASD and ADHD. They differ in not reflecting a straightforward impairment in a development-based skill that is closely related to biological maturation (e.g., motor skills) and both involve deviant functioning as much as impaired functioning. On the other hand, they have been included in this cluster because they share with the other disorders the fact that they are multifactorial in origin, are present from early life, tend to improve with increasing age but are also associated with disordered functioning that extends right into adult life. Both show a marked male preponderance. In addition, they are characterized by neuropsychological impairments of various kinds. They also often co-occur with the specific disorders of language, learning and motor function. It is a matter of judgment, but their placement in the neurodevelopmental cluster is probably more appropriate than elsewhere. It could be argued that ADHD ought to be in a cluster dealing with disruptive behavior but it does not fit well there overall.

It is not quite so obvious that tic disorders belong in this cluster but they show strong associations with other neurodevelopmental disorders (especially ADHD and, to a lesser extent, ASD) and are more common in males. Possibly, too, there may be an overlap in the rare copy number variants associated with ASD and with Tourette's syndrome (Fernandez *et al.*, 2012). Tic disorders tend to wax and wane in severity, may change in nature and can be episodic (see Chapter 56). Accordingly, they are not a really good fit into the cluster of neurodevelopmental disorders but they are probably more satisfactorily placed there than elsewhere.

Finally, neurodevelopmental impairment has been well demonstrated in relation to schizophrenia and, to a lesser extent, it has also been found to be associated with childhood onset conduct disorder. However, both fluctuate over time, they are not particularly associated with biological maturation, and there is more limited co-occurrence with other neurodevelopmental disorders. Accordingly, in our view, it is best for them to be placed elsewhere but with the proviso that the association with neurodevelopmental impairment is recognized as an important aspect of the liability. Thus, schizophrenia is placed in the psychoses cluster and conduct disorder in a disruptive behavior cluster.

Concepts of maturational lag and of plateaus in developmental progress

The concept of maturational lag derives from the extensive evidence that there are huge individual differences in the timing of

virtually all developmental functions. This is evident in relation to the timing of the eruption of teeth, the ossification of bones, and the growth spurt associated with puberty. There may well be psychological consequences of unusually early or unusually late maturation but early differences in the tempo of growth are, for the most part, not associated with any differences in outcome (Tanner, 1989). In other words, there is, ultimately, developmental catch-up. There is a similar variation in the age of first acquisition of language (Conti-Ramsden *et al.*, 2012). The question is whether children who are unusually slow to speak can, nevertheless, catch up completely. This has been studied in several different ways.

First, Bishop and Edmundson (1987) undertook a prospective longitudinal study of 87 language-impaired children who were assessed at the ages of 4, 4½, and 5½ years. Excluding those with impaired nonverbal ability, it was found that just over two-fifths showed normal language at 5½ years. These children would seem to have shown maturational lag with a full catch-up. A later follow-up at 15–16 years (Stothard *et al.*, 1998) showed that the children whose language problems had resolved by 5½ did not differ from controls on tests of vocabulary and language comprehension skills. Nevertheless, they performed significantly less well on tests of phonological processing and literary skills—suggesting that the catch-up was by no means fully complete. Those who had still got significant language difficulties at 5½ fell further behind in their language functioning over the follow-up period.

When considering the maturational lag hypothesis more generally in relation to neurodevelopmental impairments, it is clear that, although there is a general tendency for gains in function to be seen with increasing age, nevertheless, delayed early development is not usually followed by later normal functioning (Rutter *et al.*, 2006). Stanovich (1986) suggested that the answer in relation to reading might lie in a so-called “Matthew effect” whereby poor readers get worse and good readers get better as a result of literary experience boosting further language and literacy development. A key paper in that connection is one by Francis *et al.* (1996) who compared individual growth curves of 69 children with a reading disability and 334 without a reading problem. Nine yearly longitudinal assessments showed that both groups tended to plateau at about 13 years of age, with no narrowing or expansion of the gap between the groups. The difference in level, but not in trajectory, runs counter to the Matthew effect. On the other hand, there are circumstances in which an early advantage can lead to learning opportunities that have a lasting impact (Gladwell, 2008); an example is provided by the observation that outstanding sportsmen were disproportionately likely to have been born in the early part of the year. This meant that they were more likely to be selected for special coaching and this intensive special coaching led on to later increased athletic prowess.

Another key study is the Manchester language study undertaken by Conti-Ramsden *et al.* (2012), in which verbal and nonverbal skills were assessed in 242 children with a history of specific language impairment, with later assessments of both types of skills at 7, 8, 11, 14, 16, and 17 years. They found

that the developmental trajectories for language skills were generally flat over the age period studied. The nonverbal trajectories showed more individual variation and clear evidence of a slowing down in the growth of nonverbal skills in childhood to adolescence was evident in nearly one-third of the sample.

It may be concluded that the concept of a maturational lag applies to some mild specific language impairments in the preschool years but, even with this group, follow-up has shown that the recovery in some cases was less complete than originally seemed to be the case. By contrast, the concept of maturational lag does not have support with respect to more severe degrees of specific language impairment or reading. Thus, the evidence has not been supportive of a maturational lag with respect to changes after the age of 5 years and was not supportive when the overall picture of functioning was taken into account (including nonverbal as well as verbal skills).

Although the “Matthew effect” may be relevant with respect to highly intensive input, it seems much less likely to be relevant to more ordinary circumstances. The concept of maturational lag stimulated a study documenting changes in cortical thickness over time in children with ADHD, with evidence of normalization in children who had a good outcome, but not in the remainder (Shaw *et al.*, 2006, 2007). Whilst this suggests that some of the brain changes in children with the best outcomes may constitute a maturational lag, that does not apply to the remainder. In addition, however, the normalization could reflect the effects of stimulant medication, or sex differences, or the 35% attrition rate, or the lack of clinical measures in controls (making it impossible to study behavioral change in both groups). Also, the findings on cortical surface area and gyrification provided a somewhat more nuanced picture (Shaw *et al.*, 2012a, b). Furthermore, the ADHD participants were atypical in their high IQ, socially advantaged background and lack of comorbidities (apart from OCD).

Wright and Zecker (2004) have suggested that one possible explanation for the plateauing of functions (with respect to language and literacy problems) stems from the decline in neuroplasticity associated with the onset of puberty. The problem with this explanation is that brain development continues well after the onset of puberty, with higher order association areas maturing only after lower order somatosensory and visual areas (Gogtay *et al.*, 2004, see Chapter 9). Also, as Tanner (1989) pointed out years ago, the timings of development in different functions (such as bone ossification, dental eruption, and growth spurt) are only weakly associated with each other.

In the past, although it was appreciated that neurodevelopmental disorders were not due to some acquired brain lesion, there has been a tendency to suppose that the deficits may reflect something equivalent. Karmiloff-Smith and her colleagues (Karmiloff-Smith *et al.*, 2012; Karmiloff-Smith & Farran, 2012) have argued, on the basis of empirical evidence, that static models of adult brain lesions cannot be used to account for the dynamics of change in neurodevelopmental disorders. So far, there has been rather limited research on age-related changes in the manifestations of neurodevelopmental disorders but

that remains an important task for the future. The changing presentation of neurodevelopmental disorders over time are considered in the chapters on clinical syndromes (see also Chapter 1).

Concept of comorbidity and patterns of co-occurrence within the group of neurodevelopmental disorders

The term “comorbidity” has been very widely used in the literature—both scientific and clinical—but the term is often wrongly used. Comorbidity refers to the situation in which two or more separate and independent disorders are present in the same person. This could be either at the same time or it could be sequential over time. That is not the same as the co-occurrence of different symptom patterns because such co-occurrence may have several other, quite different, meanings (Caron & Rutter, 1991; Rutter, 1997).

Disorders include a diverse mixture of symptoms and many co-occurrences are likely to reflect this diversity. Whilst the neurodevelopmental disorders do not have overlapping diagnostic criteria, apparent comorbidity might arise if disorders that are defined by a main problem or symptom group are artificially subdivided. Thus, for example, both specific language impairment and reading disability comprise disorders of language. The former refers to spoken language and the latter to written language but to consider their co-occurrence in the same person as true comorbidity would not make sense. Also, although reading disability and a mathematical disability differ in important respects and are conceptually distinct, it is relatively common for children to have both (see, e.g., Geary, 1993).

Similar issues apply outside neurodevelopmental disorders, such as the co-occurrence observed among the different anxiety disorders (Kessler *et al.*, 2010) and between the various personality disorders (Lamont & Brunero, 2009). In both cases, co-occurrence across diagnostic categories is extraordinarily frequent. The situation with respect to substance use disorders is even more pronounced. Polydrug use is widespread (Darke & Hall, 1995), yet this has not been recognized adequately in classification systems.

The situation with respect to the co-occurrence of autism and ADHD is a bit different. That there is much more co-occurrence than used to be recognized is clear (see Rutter & Thapar, 2014). This is a situation in which one might want to code both as diagnoses because of the prognostic and therapeutic implications, but the overlap may involve sub threshold disorders in both cases (e.g., Clark *et al.*, 1999; Thede & Coolidge, 2007). One of the basic problems in considering co-occurrence of disorders is that, although there is reasonably good validating evidence for many diagnoses (including autism and ADHD) there is not clear separation of disorders in the way that is supposed to have been the case, for example, in terms of there being distinctive sets of risk factors and correlates (see Chapter 2).

ICD-11 and DSM-5 differ somewhat in their approach to the co-occurrence of disorders. DSM-5 has a few mixed categories when there is good evidence that they both represent a single disorder (e.g., mixed episode of mania and depression). However, the forthcoming ICD-11 has rather more mixed categories. The rationale is that the same disorder commonly gives rise to the particular mixture of symptoms. Nevertheless, the overall placement of the combination category in the classification system carries messages that may be misleading. We doubt whether that is much of a problem in the field of neurodevelopmental disorders.

The big difference between ICD and DSM lies in the approach to mixed symptom patterns that are not covered by a combination category. ICD-11, like its predecessor, implies that a profile recognition or prototypic approach is to be followed. This probably closely approximates ordinary clinical practice that involves making a diagnosis on the basis of pattern recognition but it is quite difficult to make the prototype sufficiently explicit so that they will always be used in the same way. With DSM-5, the mixture of two or more symptom patterns leads to the coding of as many diagnoses as there are patterns. This has the advantage of not requiring hierarchical judgments and of retaining a good deal of information when many patterns are present and no single category would convey them all, but it encourages an unchallenged assumption that the patterns are, indeed, truly independent, and that each can be dealt with in the same way as if there were no other problems. Coexistence of many diagnoses is undoubtedly confusing and works against the key purpose of clarity and an understanding of how the research literature may apply to a particular child. In addition, it is implausible to expect a clinician to review the presence or absence of every possible category and clinicians have been found to vary a good deal in their willingness to record symptom patterns that are not the main presentation (Rutter *et al.*, 1975).

Comorbidity is not specific to neurodevelopmental disorders or psychiatry and is not purely explained by referral bias. It is well recognized in the general medical literature that a substantial proportion of the population, especially those who are more socially disadvantaged, have two or more chronic physical diseases, a phenomenon that is often referred to as “multi-morbidity” (Barnett *et al.*, 2012; Guthrie *et al.*, 2012). The importance and practical implications of multi-morbidities are beginning to be recognized in general medicine because there is emerging evidence that it is common, not simply restricted to older individuals and has an impact on the degree of functional impairment and treatment decisions. For example, when high blood pressure (hypertension) occurs in the presence of diabetes mellitus, it is now recommended that the threshold for treatment is adjusted to a lower level (Barengo & Tuomilehto, 2012). It is being highlighted as a problem that health care organizations and treatment guidelines remain mainly geared toward single disease/disorder approaches when there is a need to explicitly take into account multi-morbidity. The same issues apply to co-morbid neurodevelopmental disorders, although as

yet there are no parallels in terms of adjusted treatment guidelines. It seems plausible however that thresholds for functional impairment and treatment for a given neurodevelopmental disorder might be lowered by the presence of a full-blown or sub-threshold comorbid condition.

There are several different explanatory models of supposed concurrent comorbidity (see Caron & Rutter, 1991) that include the contribution of shared or correlated risk factors to different disorders, as well as there being common or overlapping neural and molecular mechanisms (see Figure 3.1). It is also

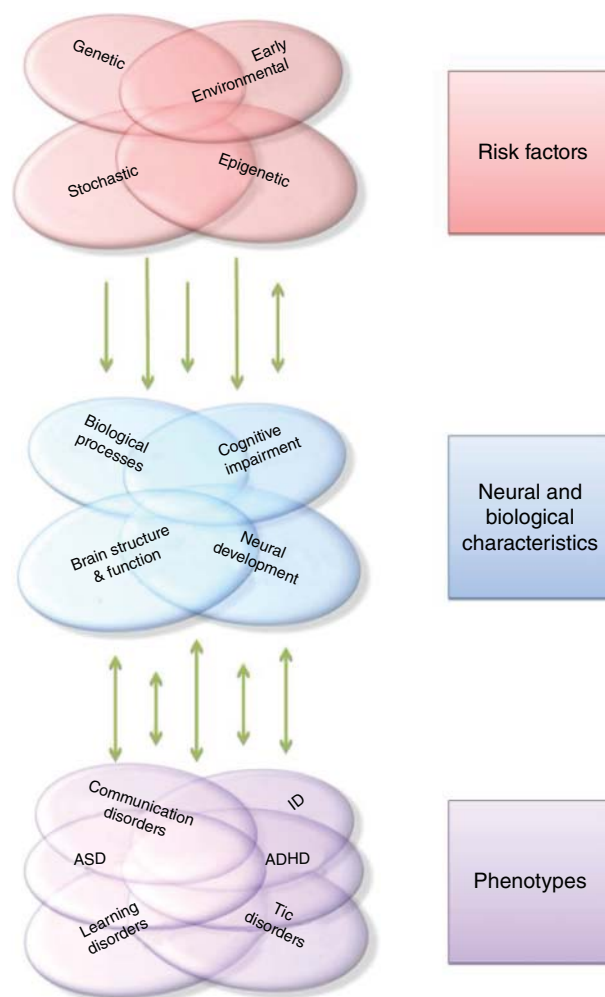

Figure 3.1 A schematic figure illustrating potential contributions to the overlap between different neurodevelopmental disorders. Clinical phenotypes as conceptualized diagnostically overlap with each other. Variation in clinical phenotypes can be conceptualized at a different phenotypic level involving “neural and biological characteristics” (e.g., variation in brain structure and function). These phenotypes can be influenced by genetic and environmental risk factors and stochastic factors that include random occurrences or insults. Epigenetic changes (see Chapter 25) involve biological modifications of the genome that can reflect early environmental exposures, DNA sequence and stochastic factors and can in turn be later modified by later experiences shaped by individual phenotype.

well recognized that neurodevelopmental disorders can be followed by new-onset psychiatric disorders later on in life that include depression and more rarely by serious forms of mental disorder such as schizophrenia and bipolar disorder (e.g., Hutton *et al.*, 2008; Galanter & Leibenluft, 2008). Later antisocial behavior/conduct disorder, criminality and substance misuse appear to be more characteristically associated with ADHD rather than typifying the developmental course of the other neurodevelopmental disorders.

Sequential comorbidity could represent different manifestations of the same underlying disease liability at different ages or represent distinctive disorders that show comorbidity because of shared risks and mechanisms. It could also mean that some subforms of neurodevelopmental disorders in some individuals are actually the early precursors of illness such as schizophrenia and bipolar disorder, especially early onset cases (see disorder chapters). However, most people with neurodevelopmental disorders do not develop such illnesses and the neurodevelopmental problems are also not “replaced” by these second disorders. Links between neurodevelopmental disorders and later onset psychiatric disorders could also arise from psychosocial risks created by specific features of these early neurodevelopmental problems. For example, early neurodevelopmental impairments could create or influence stressors such as peer rejection, social isolation, parental hostility and academic failure that in turn might play a contributory role in unmasking liability for a new later onset psychiatric disorder (see Chapter 12). Evidence on this possibility, however, is mainly lacking.

The co-occurrence of different neurodevelopmental disorders due to shared risks and biological characteristics

Genetics

All of the neurodevelopmental disorders are highly heritable (Thapar *et al.*, 1999; Stromswold, 2001; Deary *et al.*, 2009; O’Rourke *et al.*, 2009; Willcutt *et al.*, 2010; Ronald & Hoekstra, 2011) and shared genetic risks (see Chapter 24) contribute to much of their co-occurrence. Although most of the genetic liability appears to be shared across different neurodevelopmental disorders and traits, there are also disorder-specific influences and the liability extends to disorders outside the neurodevelopmental cluster (Lahey *et al.*, 2011).

For example, the average genetic correlation (meaning the part of the trait correlation that is genetically mediated) between reading and language, reading and mathematics, and language and mathematics is around 0.70 (Haworth & Plomin, 2010). The genetic correlation between ASD and ADHD dimensions is similarly high, estimated at between 0.54 and 0.87 (Ronald *et al.*, 2008; Lichtenstein *et al.*, 2010). It is the inattentive aspects of ADHD that show the most prominent genetic overlap with

reading disability and arithmetic disability (e.g., Paloyelis *et al.*, 2010; Willcutt, *et al.*, 2010; Greven *et al.*, 2011; Greven *et al.*, 2012). Genetic liability for ASD similarly appears to confer broader risks of language and learning impairments in relatives of those affected; what is known as the broader autism phenotype (Rutter & Thapar, 2014). Shared genetic risks again explain much of the covariation between IQ and other neurodevelopmental phenotypes, for example between IQ and ADHD and between IQ and ASD traits (Hoekstra *et al.*, 2010; Ronald & Hoekstra, 2011). In one Scandinavian twin study that simultaneously assessed a broader set of neurodevelopmental categories, shared genetic risks were found to contribute to ADHD, ASD and motor co-ordination problems, as well as tics (Lichtenstein *et al.*, 2010).

Much the same conclusions derive from molecular genetic studies. For example, one variety of genetic mutation, large rare copy number variants (subtle chromosomal deletions and duplications; CNVs), is associated with multiple different types of neurodevelopmental disorders that include ASD, ADHD, and ID (Guilmatre *et al.*, 2009; Williams *et al.*, 2010; Sullivan *et al.*, 2012a, b; Thapar *et al.*, 2013) and also a broader range of disorders outside the neurodevelopmental cluster, notably schizophrenia and epilepsy. Another example of shared genetic risks influencing multiple neurodevelopmental disorders is provided by *CNTNAP2*, a gene that has been implicated in ASD, severe ID and speech and language problems (Peñagarikano & Geschwind, 2012).

The finding that genetic influences are uninformative on the grouping of neurodevelopmental disorders arises from several different considerations. First, most genes are pleiotropic (see Chapter 24). The original notion that each gene affects just one protein with a single effect has proved mistaken. Second, genes affect proteins and not psychiatric categories. There will be effects on disorders, but these are likely to arise from influences on biological pathways that lead to disorder only indirectly. Third, it has been found that different diagnostic categories are not as separate as had once been thought (see Chapter 2; also, Sullivan *et al.*, 2012a, b; Cross-Disorder Group of the Psychiatric Genomics Consortium, 2013; Hamshere *et al.*, 2013a, b; Lahey *et al.*, 2011).

Environmental influences

The same issues, including lack of diagnostic specificity, apply to environmental influences (McMahon *et al.*, 2003). However, there are two disorders that may be considered neurodevelopmental (namely disinhibited disorder of social regulation and quasi-autism) which do show a relatively specific association with institutional deprivation (see Chapter 58). Institutional deprivation that persists beyond the age of 6 months has been found to be associated with a major adverse effect on head growth (and therefore, by implication, brain growth). This applied to institutional deprivation that was unaccompanied by subnutrition, as indexed by body weight

(Sonuga-Barke *et al.*, 2010). Both quasi-autism and disinhibited disorder of social regulation had an association with institutional deprivation that was as strong at 15 years as it had been at 11 years and before that at 6 years and 4 years. Moreover, both disorders showed a strong degree of persistence, with use of professional services, at least up to early adult life.

Shared biological and neural characteristics

There is growing interest in the extent to which early epigenetic changes (see Chapter 25) are involved in the pathogenesis of different neurodevelopmental disorders, given that they are subject to alteration by prenatal and early life exposures (Relton & Davey Smith, 2010), as well as by inherited genes. Epigenetic mechanisms might also help explain how the same sets of risk factors/liabilities result in different clinical features. For example, one genome-wide methylation study of monozygotic twins (who carry the same sets of genetic risk factors) with autism found that patterns of methylation (implying different levels of gene expression) differed between affected and unaffected twins from discordant pairs (Wong *et al.*, 2014).

The cognitive deficits that are common in neurodevelopmental disorders (e.g., Rommelse *et al.*, 2011; Taylor *et al.*, 2012) are observable by early-mid childhood and tend to affect multiple cognitive domains (e.g., executive dysfunction, social cognition) and have often been found to be associated with alterations in brain structure and function (e.g., Cherkasova & Hechtman, 2009; Caylak, 2009; Rykhlevskaia *et al.*, 2009; Anagnostou & Taylor, 2011; Kaufmann *et al.*, 2011; see disorder chapters). Although some cognitive and imaging features are considered to be highly characteristic of one disorder (e.g., impaired theory of mind in ASD or response inhibition in ADHD; Rutter, 2011; Crosbie *et al.*, 2013), there are recognized and prominent overlaps with certain types of deficits crossing diagnostic boundaries (e.g., Rommelse *et al.*, 2011). Cognitive deficits are not however a distinctive feature of neurodevelopmental disorders alone. They characterize many different psychiatric disorders, including the most severe forms of mental illness.

The co-occurrence among neurodevelopmental disorders, shared cognitive and neural features, as well as common genetic risks highlights the possibility of there being overlapping biological processes. Findings from genetic studies have begun to be integrated with knowledge of systems level biology to examine what sorts of shared and unique biological and molecular mechanisms underpin different neurodevelopmental conditions (e.g., Cristino *et al.*, 2014). For example, studies of autism have highlighted genes involved in synapse formation and maintenance and chromatin regulators that are essential for developmental processes, including those involving the brain (Ben-David & Shifman, 2012). The same biological processes have also been implicated as being involved in ID. A number of studies have now highlighted biological commonalities between ASD, ID and ADHD, as well as with schizophrenia.

Important patterns of difference between these disorders are also being observed (e.g., Guilmatre *et al.*, 2009; Cristino *et al.*, 2014). Biological differences between neurodevelopmental disorders would be expected even from already well-established knowledge on medication. Whilst stimulants are effective for ADHD symptoms, they do not help ASD or tics. Antipsychotic medications, although helpful in reducing tics, are not effective in the treatment of core features of ADHD or ASD (see disorder chapters). A recent meta-analysis (Weisman *et al.*, 2013) suggested that alpha-2 agonists were beneficial in treating tics in patients with ADHD but not in those without ADHD.

Sex differences

A striking and consistent feature of neurodevelopmental disorders is that they tend to show a male excess. Specific arithmetical problems may be different in this regard (but see Landerl & Moll, 2010 for a listing of contradictory reports). Whilst the imbalanced gender ratio is more pronounced in those referred to services, it is still evident in population-based studies, and thus not simply explained by an artifact of clinical recognition or referral to services (Lichtenstein *et al.*, 2010). Despite being an established observation, the reasons for a male excess remain unknown (Rutter *et al.*, 2003). What is striking, however, is that male preponderance is mainly a feature of early onset neurodevelopmental disorders, whereas female preponderance is mainly found with adolescent or adult onset emotional or eating disorders. The marked contrast is very likely to have a biological substrate, although what that is remains unidentified.

Three levels of causes have to be considered (Rutter *et al.*, 2003). First, the distal basic starting point has to implicate some aspect of the genetic difference between males and females. Nevertheless, of themselves, the genetic distinctions do not provide an explanation for the sex differences in mental disorders. Is this because genetic variation on a sex chromosome is associated with a risk variable, because of a hormonal effect, or because males are more exposed to, or are more vulnerable to, environmental stressors? These intermediate consequences constitute the second level of causes. There then has to be a third level in which additional proximal risk or protective factors are more directly involved. To explain the sex difference, these proximal features must meet three criteria: (1) evidence that the risk factors do indeed differ between males and females; (2) evidence that within each sex they provide risk for, or protection against, particular disorders; and (3) evidence that when their effect is included in a causal model, they either reduce or eliminate the sex difference. No variables have met all these criteria, but see Moffitt *et al.* (2001) for an approach to this research strategy.

A focus on these different causal levels can be instructive. For example, Angold (2008) showed that the greater underlying liability to depression in females was a function of sex hormone levels but the hormones did not act to provoke the onset of

depression. It might be thought that the pubertal surge of male sex hormones would lead to an increased male preponderance of antisocial disorders in adolescence, but, in fact, the rise in adolescence tends to be greater in females (Moffitt *et al.*, 2001).

A polygenic liability threshold model (meaning one based on multiple genes working dimensionally, with disorder manifest only above a certain threshold) provides another framework for considering sex differences (Falconer, 1965). According to this model, gender differences should be explicable on the basis of differing thresholds for males and females and affected females should require a higher polygenic loading to show the disorder if the phenotype occurs less commonly in females. There is some supporting evidence in the case of ADHD and ASD (Hamshere *et al.*, 2013a, b; Rhee and Waldman, 2004; Szatmari *et al.*, 2012). However, the opposite pattern was found with specific language impairment (SLI) (Conti-Ramsden *et al.*, 2007). There are, as yet, too few data for any general conclusions on the validity of polygenic liability threshold models. There has also been a growing interest in the possible contributions of sexually dimorphic patterns of gene expression (see Chapter 25; also Jessen and Auger, 2011) but further evidence is required to consider the possibility.

We urge that systematic research into sex differences in psychopathology should be a priority, and this need extends well beyond neurodevelopmental disorders. An understanding of the causes of the sex differences may provide a crucial understanding of the causal processes for mental disorders within each sex. Of course it cannot be assumed that the mechanisms involved in the difference between groups (in this case the two sexes) will be identical with the mechanisms responsible for individual differences within each group but, equally, it would be foolhardy to assume that this will necessarily be different. Systematic testing of both possibilities is required.

Does neurodevelopmental impairment have the same meaning in all disorders?

In our introduction to this chapter we considered the commonalities among disorders in the neurodevelopmental cluster. We turn now to the opposite question—namely, possible heterogeneity. The first sub grouping comprises learning and language disorders because these constitute the prototype of disorders that are distinctive in being accompanied by cognitive impairments, associated with biological maturation, tending to improve with increasing age, and lacking the remissions and relapses that are a feature of most multifactorial mental disorders. In these disorders, the neurodevelopmental impairment constitutes an intrinsic part of the disorder.

ID is generally classed as a learning disorder but it differs markedly from reading disorder and mathematics disorder in several key respects, although there is great overlap with both. First, there is massive etiological heterogeneity and a meaningful

subdivision between severe and mild disorders in terms of that heterogeneity. Clearly, there is neurodevelopmental impairment in both, but its meaning is likely to be very different, according to the presence/absence of a medical syndrome that constitutes the major cause of ID. Mild ID that is *not* associated with a specific medical condition will involve neurodevelopmental impairment but it will reflect multiple origins, and not just one major cause. ID obviously belongs in the neurodevelopmental cluster but it has more differences than similarities with respect to other disorders in the cluster.

The situation with ADHD and ASD is quite different in that the key core features *do* show remissions and relapses in some cases. The extent to which each condition exhibits neurodevelopmental impairment shows considerable individual variability. When such impairment is present, it seems to constitute an intrinsic feature of the disorder, and not some separate comorbidity. However, the greatest justification for their placement in the neurodevelopmental cluster is that they usually persist into adult life and, when they do, they present considerable problems in service provision because so few adult psychiatrists (or clinical psychologists) have experience in dealing with the clinical problems that derive from the persistence of an early onset neurodevelopmental disorder. Typically, few child professionals are familiar with either manifestations in adult life or the operation of services for adults. As a result, many individuals with either ASD or ADHD receive inadequate care and treatment. Much the same applies to language disorders that persist into adult life.

The situation with both schizophrenia and conduct/dissocial disorder is different yet again. There is good evidence that schizophrenia is often preceded by impairments in either language or motor development or both, and below average IQ scores (Cannon *et al.*, 2002). These impairments are evident at all ages during childhood but it is not known if there is consistency at an individual level. The particular individual cognitive pattern is not diagnostically distinctive and it remains unclear whether the impairments are a function of the genetic liability for schizophrenia (see Chapter 57). Conduct/dissocial disorder is associated with hyperactivity/impulsivity when the onset is in the childhood period (see Chapter 65) but the pattern is not diagnostically distinctive and, as with schizophrenia, the neurodevelopmental impairment is probably a function of the genetic liability to conduct/dissocial disorder. Unlike the situation with ASD and ADHD, the same sort of clinical problem does not tend to be seen in the transition to adult life. For all these reasons, we conclude that, although neurodevelopmental impairment is associated with both disorders, they are probably best grouped outside the neurodevelopmental cluster.

The situation with respect to tics is different yet again. The association with neurodevelopmental impairment is strongest in the case of multiple tics and weakest in the case of simple single tics, but the overall association is both weak and not

diagnostically distinctive (see Chapter 56). The meaning of the impairment remains unclear.

Clinical value of neurodevelopmental impairment concepts

There are three main clinical gains from focussing attention on neurodevelopmental impairment. First, it has the practical importance of alerting clinicians to the need to appreciate the importance of paying attention to the challenges in assessment and intervention of the functional deficits associated with neurodevelopment in disorders whose defining features have a different focus (as would be the case with ASD, ADHD, and schizophrenia). Second, with respect to particular individual disorders, it highlights special issues. Thus, in the case of schizophrenia it draws attention to the early risk features in the preschool years of a mental disorder that becomes fully manifest only in early adult life. With respect to CD/dissocial disorder, it underlines the fact that it does not just represent “naughtiness.”

Third, it emphasizes the need to broaden research perspectives beyond single disorder specialism in order to determine how risk and protective factors may operate in similar ways across diverse disorders. For example, the strong male preponderance seen with ASD led to the suggestion that autism might represent the extreme male brain (Baron-Cohen, 2003). The observation that ADHD, dyslexia and several other disorders also show both a similar sex difference and neurodevelopmental impairments suggests that there may be causal pathways that span different disorders.

Finally, heterogeneity in the meaning of neurodevelopmental impairment is a reminder that because we give the same name to what is found in autism, schizophrenia and dyslexia should *not* lead us to assume that the same mechanisms apply. Because there is substantial co-occurrence among neurodevelopmental disorders, parents may be puzzled and concerned when different experts give different diagnoses to their child. Thus, when the child’s problem concerns a mixture of ADHD and ASD symptoms, experts may vary as to which diagnosis they use, even though, in reality, they do not really differ on the nature of the problem. This is an issue noted years ago in the WHO seminars that gave rise to a multiaxial classification (Rutter *et al.*, 1975). What is new is the appreciation that the issue applies within axes and not just between them. Families need to be helped to understand the implications of the lack of clear water between diagnostic categories.

Acknowledgments

We are extremely grateful to Joanna Martin and Miriam Cooper for their invaluable assistance with the literature search, figure, helpful comments and suggestions.

CHAPTER 4

Conceptual issues and empirical challenges in the disruptive behavior disorders

Jonathan Hill¹ and Barbara Maughan²

The scope of this chapter

The term “disruptive behavior disorders” refers to a broad set of aggressive, disruptive, oppositional, and anger-related behaviors. They are commonly contrasted with “emotional disorders,” yet as we shall argue, emotionality is also central to the causes and maintenance of many behavioral problems. A core paradox about childhood disruptive behavior problems is that while they are widely viewed as having social origins, reflecting parental and societal failures, and so readily amenable to social, educational, economic or political solutions, they are also among the most intransigent and harmful of known mental health disorders. A review of conceptual issues has to embrace both sides of this paradox. On the one hand many of these problems represent a failure of socialization in childhood and then in adult life, so that sufferers find themselves in disadvantageous situations, such as social isolation and school exclusion in childhood, youth offender institutions in adolescence and prison in adult life. This socialization process might be altered by changes in social, educational, or economic conditions. On the other hand, children with behavioral problems differ from other children in multiple ways, genetic, temperamental, physiological and social cognitive, and even early in childhood many do not gain from improvements in environmental conditions.

What is the phenotype?

Identifying a phenotype that is both reasonably homogenous and also distinct from other phenotypes is central to understanding the origins, underlying processes, treatment needs, and long-term outcomes of any disorder. The identity of the phenotype in the broad area of disruptive behavior problems is, however, a focus of continuing discussion. This is potentially

of value, although it needs to be borne in mind that behavioral phenotypes, however homogenous, may not map precisely on to biological or psychological processes. Furthermore, a common set of processes may underpin diverse behaviors, in which case more purchase may be obtained from a broad characterization of the phenotype.

The American Diagnostic and Statistical Manual (DSM-5; American Psychiatric Association, 2013) distinguishes between oppositional defiant disorder (ODD) and conduct disorder (CD). Behavioral criteria for ODD are: angry and resentful, loses temper, argues with adults, defies and refuses to comply with requests and rules, annoys people, blames others, touchy and easily annoyed, spiteful or vindictive. The criteria for CD are too numerous to list; in contrast to ODD, however, they include aggressive behaviors such as: often bullies, threatens, or intimidates others, and often initiates physical fights, along with rule-breaking behaviors such as lying and stealing, and “serious violations of rules.” See Chapter 65.

The ODD/CD distinction is limited as a tool for investigating heterogeneity in disruptive behavior problems because, in contrast to the ODD items, many of the CD criteria are age-dependent, with items such as “has used a weapon that can cause serious harm” or “has forced someone into sexual activity” rarely being encountered before adolescence. Heterogeneity has also been identified, however, using the contrast between “overt” disruptive, oppositional and aggressive behaviors, and “covert” behaviors such as theft and vandalism. Covert behaviors are rarely seen in young children at ages when aggression and opposition are already common, and show increases in later childhood and adolescence. Within overt behaviors, differentiations are often made between aggression, oppositionality, and anger-proneness or irritability; further demarcations of physical aggression differentiate between reactive aggression, which occurs in response to actual or perceived provocation,

and proactive aggression, in which the perpetrator takes the initiative in attacking another.

These characterizations seek to identify heterogeneity in behaviors, not in children, and indeed in most instances they are highly correlated, for example, overt with covert behaviors (Snyder *et al.*, 2012), and reactive and proactive aggression (Polman *et al.*, 2007). By contrast, the construct of “callous unemotional” traits, characterized by a lack of responsiveness to others’ distress, has been used to demarcate subgroups of children (Frick & White, 2008). Studies vary considerably in the ways they characterize disruptive behavior problems, some using broad brush measures such as the aggression scale of the Child Behavior Checklist (which includes aggression, oppositionality, and anger-proneness), others making specific contrasts, for example between overt and covert behaviors, or disruptive children with or without callous unemotional traits. It is extremely unusual to find studies that address more than one of these contrasts in the same analyses.

Finally, we should note that the search for satisfactory phenotypes is not confined to heterogeneity within disruptive behaviors alone. Other emotional and behavioral syndromes, most notably perhaps attention deficit and hyperactivity disorder (ADHD) and depressive disorders, are frequently associated with disruptive behavior disorders. There are a number of much-debated possible explanations for this, including that it reflects true comorbidity (the co-occurrence of different disorders); that there is a broader phenotype extending beyond disruptive behavior problems; or that combinations of disorders are themselves phenotypes, distinct from their component parts.

The starting point: well-replicated findings

The attempt to understand the origins and nature of disruptive behavior problems must start with five well-replicated findings (Table 4.1).

The first and second of these findings—that disruptive behavior problems commonly persist, and that they are associated with criminality and social dysfunction over a broad front—were first described by Lee Robins in her 1960s’ follow-up of children seen in child guidance clinics 30 years earlier. In her book “Deviant Children Grown Up” (Robins, 1966), she shows that children with disruptive behavior problems commonly, as adults, showed persistent violence and other illegal behaviors, and that they also had problems that extended well beyond specifically antisocial acts. In particular, they often had unstable lifestyles characterized by brief relationships, job instability, and impulsive, reckless behaviors, summarized in the DSM criteria for Antisocial Personality Disorder in adults.

Subsequent studies of general population cohorts have confirmed that disruptive behavior problems seen in young children commonly persist, and that they are associated with increased risks not only for antisocial and poor interpersonal outcomes, but also for many psychiatric disorders, notably, depression, anxiety disorders, PTSD, and alcohol and drug

Table 4.1 Well-replicated findings for disruptive behavior problems.

1.	Disruptive behavior problems commonly start before age 2 years and may persist over many years
2.	In adult life they are associated with criminality; with the behavioral and social difficulties identified as DSM Antisocial Personality Disorder; and with psychiatric disorders such as substance misuse and depression
3.	Rates of antisocial and delinquent behaviors increase markedly during adolescence and fall in adult life
4.	Between 50% and 70% of children with disruptive behavior problems show improvement during childhood, but some continue to have adjustment problems
5.	Disruptive behavior problems are more common in boys than in girls

misuse (Odgers *et al.*, 2008). Many of these studies have used repeated measurements across childhood to generate developmental trajectories of behavior problems and to assign children to those trajectories (see e.g., Cote *et al.*, 2006). There has been substantial convergence among studies of overt behaviors (either aggressive or oppositional defiant), toward there being a group of children who start high and remain high (Tremblay, 2010). Although the age of onset of this persistent high group is unclear, the first data points in such studies are commonly around 18–24 months, suggesting that children with overt behavior problems manifest them as soon as they have the physical capability to hit or oppose! General population studies have not identified groups of children with new onsets of aggression or oppositional defiant behaviors from toddlerhood up to puberty; however, there may be further groups that can be identified in different samples, for example of clinically referred children. The third well-replicated finding is that rates of antisocial and delinquent behaviors increase dramatically across the teens, then fall back again in early adulthood (Moffitt, 1993). Fourth, the majority of children with early onset disruptive behavior problems (typically estimated at between 50% and 70%) do not show persistence of those problems into adult life, though men in particular may show some isolated difficulties in other domains (Odgers *et al.*, 2008). And finally, most disruptive behavior problems are more common in boys than girls.

What do we need to explain?

It follows from these findings that the search for the causes of childhood disruptive behaviors needs to begin with early life, including pregnancy and infancy, and that we need to explain not only how they are initiated but also why they persist. The question of persistence is especially acute here because we need to be able to explain why problems that are so clearly maladaptive, and attract negative responses from others, are also so apparently resistant to change. We consider four distinct possibilities.

First, maladaptive behaviors have their origins in, and are maintained by, environmental adversities such as physical

abuse to which children respond with their own aggression (Kim-Cohen *et al.*, 2006), or there are social rewards for disruptive behaviors (Snyder *et al.*, 2012). Persistence arises either from persistence of the unfavorable environment, from the establishment of inaccurate social cognitive schemas (Dodge *et al.*, 1995) or from consolidation of social learning.

Second, there is an enduring deficit or abnormality, such as a failure of emotional responsiveness to others' expressions of fear, that contributes to indifference to others' distress (Blair, 2008).

Third, disruptive behavior problems are motivated. The child's attempts to find a solution to threats in the environment lead to an adaptation that also creates a vulnerability. Disengaging attention from threat, for example, reduces fear, but may also lead to impoverished monitoring of social interactions, increasing the likelihood of using coercive solutions (Derryberry & Rothbart, 1997). Aggression is then maintained by the child's motivation to solve the problem of being frightened.

Finally, disruptive behaviors arise from the effects of genetic, physiological or behavioral variations and of epigenetic mechanisms (see Chapter 25). Such variations may have been retained in evolution because they are adaptive under some environmental conditions, even though they confer risk under others (Ellis *et al.*, 2011). The paradigm case, the "fetal origins hypothesis," proposes that low birth weight reflects an *in utero* adaptation to an anticipated food-scarce environment, which then creates vulnerability to obesity, hypertension, heart disease, and diabetes in Westernized high calorie environments (Barker, 1998). It seems that several early developmental mechanisms for psychopathology may be associated with biological variations that confer either advantage or risk, depending on the environments encountered. It has been argued that variations in children's susceptibility to the environment may have evolved to ensure that some individuals are not seriously affected if they encounter adverse environments, while others are well placed to take advantage of favorable environments (the differential susceptibility hypothesis, Belsky & Pluess, 2009). Findings based on predictions from fetal programming have not all shown the predicted associations, but associations have been found between low birth weight and adolescent depression (Costello *et al.*, 2007), and prenatal maternal anxiety and disruptive behaviors in offspring (O'Connor *et al.*, 2003, O'Donnell *et al.*, 2014). In a similar way, genetic (Pickles *et al.*, 2013), behavioral (Belsky & Pluess, 2009) and physiological (Obradovic, 2012) reactivity appears to confer advantage or vulnerability in a context-dependent manner.

Unraveling risks for disruptive behavior problems

Numerous risk factors are associated with childhood behavior problems. The list includes parental criminality and psychiatric disorders, prenatal anxiety, smoking in pregnancy, single parent status, marital discord, partner violence, poor parental

supervision, harsh parenting, child physical abuse, social deprivation, neighborhood violence, low IQ, language delay, low school achievement, large family size, low family income, anti-social peers, high delinquency-rate schools, and high crime neighborhoods (Murray & Farrington, 2010). Plausible causal mechanisms have been proposed for each, but associations among them are common, and many are likely to be accounted for by third variable effects. For example, there is a widely replicated association between smoking in pregnancy and disruptive behaviors, with plausible causal explanations (Wakschlag, 2002). However, mothers who smoke during pregnancy differ in many respects from mothers who do not; they are more likely to have a history of antisocial behavior, less education, and less income, all of which could explain their children's antisocial behavior. Studies designed to deal with such confounders make use of strategies such as sibling comparisons (where the confounders are the same for each sibling but exposure to smoking varies), and propensity score matching, where smokers and non smokers are matched on risks for smoking, and then the effect of smoking is examined (Jaffee *et al.*, 2012). Family processes such as marital discord and harsh parenting also commonly reflect parental antisocial problems, suggesting that associations between parenting and child disruptive behaviors may in part arise from common genetic effects. Twin and adoption designs can deal with many of the possible genetic confounds (see Chapter 24) and the study of natural experiments has been valuable (see Chapter 12). Asbury *et al.* (2003), for example, showed that differences in the harshness of parenting experienced by identical twins predicted disruptive behaviors, consistent with an environmentally-mediated effect. Independent effects of parental hostility on child behavior problems have also been shown in children conceived by in vitro fertilization (and so genetically unrelated to their parents, Harold *et al.*, 2012), and twin studies have also supported bidirectional effects, with, for example, low child self-control predicting harsh parenting, and harsh parenting predicting disruptive behavior problems, even after accounting for genetic contributions (Cecil *et al.*, 2012). The process of testing alternative explanations for associations of possible risk factors with disruptive behavior problems is crucial to establishing causality (see Chapter 12). These will however remain broad-brush unless more specific hypotheses are developed regarding mechanisms. Here, demarcating contrasting pathways is likely to be key. We will illustrate this by considering three possible pathways, each plausible, each with some supporting evidence, but where in each case the evidence still falls well short of a coherent or complete account. These pathways are illustrated in Figure 4.1.

Anger-proneness in interaction with adverse parenting—a high reactive pathway

We begin with a "high reactive" pathway, in which the vulnerability is created by a combination of temperamental infant anger-proneness and parental negative intrusive behaviors that further increase the negative mood of the child. Marital discord,

Low reactivity is indicated by the dotted line and high reactivity by the solid line.
Upward direction of a line denotes increasing low or high reactivity

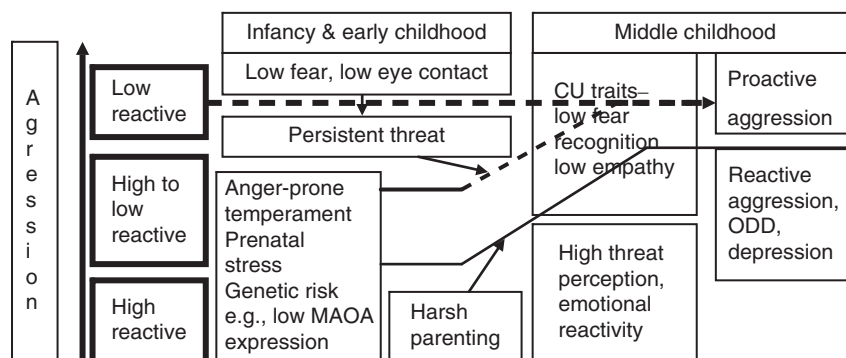

Figure 4.1 Summary of possible pathways to disruptive behavior problems.

partner violence, parental irritability associated with depression, and physical abuse may also contribute to increased emotional dysregulation. Parental negativity may arise both from evocative interactions whereby the infant's intense prolonged displays of anger lead to frustration and parental anger, and shared genetic influences on parent and child negative emotionality. The child may come to respond not only to actual parental threats, but also to perceived threat from apparently innocuous behaviors. Later in childhood, the child's emotional reactivity also leads to conflict with peers and other adults, creating a pervasively hostile environment; those who are able to, avoid contact with the child, leading to social isolation or associations only with children with similar problems. Difficulties in managing social interactions are compounded by low verbal IQ and limitations in flexible adaptive planning associated with prefrontal deficits. The child's aggression is angry and reactive.

Empirical studies in this area vary in the measurement of early temperament, some using the broad characterization of "difficult" temperament, others negative emotionality, and yet others, anger-proneness (see Chapter 8). The available studies are nevertheless consistent in finding an interaction between negative emotionality and parenting during infancy in the prediction of later behavior problems. High negative emotionality in the presence of high parental negativity, or low sensitivity, predicts later disruptive behavior problems (Bradley & Corwyn, 2008; van Aken *et al.*, 2007). However, in line with the differential susceptibility hypothesis, while children with high negative emotionality who received less supportive parenting have the highest rates of disruptive behaviors, those with the most sensitive parents have the lowest levels. It is possible that high negative emotionality creates the conditions in which the skills of emotion regulation are acquired, provided parents are able to respond sensitively. Independent contributions of parental depression (Barker *et al.*, 2012), marital discord (Bornoalova *et al.*, 2014), and physical abuse (Jaffee *et al.*, 2004) to the prediction of disruptive behavior problems have been shown in a range of studies. However, the interplay between parental characteristics, parenting, and temperament has not received much attention. In one of the

few studies to examine temperament, parenting, and marital discord, child anger-proneness in interaction with low parental guidance predicted externalizing symptoms, as did lack of partner support (Smeekens *et al.*, 2007). The model predicts that this developmental pathway should lead specifically to reactive, anger-related aggression. Despite some support for associations between physical abuse, increased threat detection, and reactive aggression (Dodge *et al.*, 1995; Dodge & Pettit, 2003), links between early anger-proneness, parenting and family processes have not yet been described. Indeed it is striking that in spite of the considerable evidence for heterogeneity in disruptive behavior problems, studies of the contributions of early developmental processes rarely move beyond broad-brush assessments of externalizing or oppositional defiance/aggression as outcomes.

Also relevant to this pathway, maternal anxiety and depression during pregnancy have been found to predict childhood behavior problems after controlling for postnatal environmental factors (O'Connor *et al.*, 2003; Barker *et al.*, 2011a), and prenatal maternal anxiety predicts persistence from childhood to adolescence (Barker & Maughan, 2009). These studies have not examined specific mechanisms linking prenatal exposures to behavior problems, but there are good reasons to predict effects on an anger-prone pathway. In animal studies, prenatal stress is associated with emotional and hypothalamic-pituitary-adrenal (HPA) axis hyper-reactivity, and in humans, maternal cortisol during pregnancy predicts infant cortisol reactivity to a stressor (Davis *et al.*, 2011). Prenatal maternal depression predicts infant temperamental negative emotionality (Davis *et al.*, 2007), and this association is modified by postnatal maternal stroking, consistent with effects of tactile stimulation on gene expression in rodents (Sharp *et al.*, 2012). There may also be specific contributions to this pathway from environment-dependent effects of gene variants such as those of MAOA. Several studies have found that a polymorphism of the MAOA gene, associated with low gene expression, predicts antisocial behaviors in adults (Caspi *et al.*, 2002) and behavior problems in children (Kim-Cohen *et al.*, 2006) only among those exposed to maltreatment. Thus far studies have not examined whether

MAOA G×E contributes to specific pathways to disruptive behaviors; however, animal and human studies provide some indications that low MAOA gene expression is likely to be associated with increased negative emotionality (Meyer-Lindenberg & Weinberger, 2006). This is consistent with findings that the MAOA variants interact with life events during pregnancy to predict negative emotionality at 5 weeks (Hill *et al.*, 2013), and with maternal sensitivity at 7 months to predict anger proneness at 14 months (Pickles *et al.*, 2013). These are the first reports of a possible role for MAOA activity status in relation to infant negative emotionality, and replication studies are needed (see Chapter 24).

Lack of responsiveness to others' distress—a low reactive pathway

We turn next to the subgroup of children and adolescents with persistent disruptive behavior problems who are reported by parents and teachers as lacking concern for others' distress, often referred to as showing "callous unemotional" (CU) traits (Frick & White, 2008). (The related concept of psychopathy is covered in Chapter 68). Among adolescents with disruptive behaviors CU traits are predictive of more severe aggression, and more persistent antisocial behavior problems, and there is emerging evidence that this is also the case in children. Individuals with CU traits differ from other disruptive children in multiple ways: they show poorer recognition of sad and fearful faces, lower anxiety levels, superior verbal IQ, and their families have fewer psychosocial risks such as marital discord (Viding *et al.*, 2012). They also show reduced activation of the amygdala in response to viewing fearful faces (Jones *et al.*, 2009), which may contribute to lower empathic responses to others' distress. The prominence of deficits in responding to others' emotional states associated with CU traits poses interesting questions regarding possible overlap with autistic spectrum disorder (ASD). Conceptually, however, there are two major differences. First, CU traits are thought to be associated with lack of responsiveness to sadness or fear, while in the autistic spectrum there are difficulties in understanding emotions in general. Second, the main deficit associated with CU traits is of emotional *responsivity* to distress (affective empathy), while autistic traits are associated with a lack of *understanding* of others feelings—that is, cognitive empathy. This has been examined in a comparison of three groups of clinic-referred boys with ASD, and with conduct disorder with and without CU traits, and a non clinical control group. The children were shown video clips of emotionally loaded situations, and asked how the protagonists felt, why they felt that way, and how they themselves felt watching each video sequence. Children with ASD did less well than others in providing an account of the reasons for the protagonists' feelings, while those in the CU traits group described the lowest levels of emotions on watching the videos (Schwenck *et al.*, 2012).

There are few developmental studies of the infancy origins of CU traits, but several lines of evidence suggest possible elements

in the pathway. There appears to be a distinctive genetic contribution to CU traits, which may be stronger than for disruptive behavior problems more generally (Viding *et al.*, 2005). Furthermore, in contrast to other forms of behavior problems, the evidence from most studies is that CU traits are not associated with harsh parenting in community samples in childhood (Frick & Viding, 2009). It is possible therefore that a major contribution to CU traits comes from an inherited vulnerability, for which there are several candidates.

First, vulnerable infants may make less eye contact with parents than other children. Boys with high CU traits show impaired attention to the eye region when viewing standardized emotional faces, but show normal patterns of fear recognition when instructed to focus on the eye region (Dadds *et al.*, 2011), suggesting that the reduced eye contact has a causal role in reduced emotional responsiveness. Boys with high CU traits also show lower eye contact in free play, and lower eye contact is associated with impaired fear recognition and empathy. Dadds and colleagues have proposed that reduced eye contact may lead to less engagement with caregivers and hence fewer opportunities to acquire an understanding of others' emotions.

Second, lack of emotional responsiveness to others' emotions may be increased by temperamental fearlessness because children miss out on the developmental advantages conferred by the experience of fear. Several studies of normally developing children have shown that infant fearfulness is associated with greater evidence of conscience and guilt (Kochanska *et al.*, 2002). Fearlessness may therefore inhibit the development of responsiveness to others' distress. Fearlessness may also be associated with reduced behavioral inhibition. Gray (1987) proposed that the 'Behavioural Inhibition System' is activated by actual or anticipated punishment, leading to anxiety which can be avoided by not behaving in ways that increase the likelihood of being punished. Reduced activation of behavioral inhibition removes a brake on bad behavior, and also makes punishment a less effective means of regulating a child's behavior. Fearlessness may also reduce fear conditioning, such that stimuli that are not inherently aversive come to elicit fear after being paired with unconditioned stimuli. In normal development, the pairing of mild reprimands with strong forms of punishment may lead to the effectiveness of low key adult behaviors in regulating behaviors. This may be impaired in the development of CU traits. Findings of reduced fear conditioning in male antisocial adolescents (Fairchild *et al.*, 2008) are consistent with this possibility, although it remains to be established whether this is specific to CU traits. The infant who experiences fear infrequently or at low levels is also less likely to look to a parent for comfort in the face of threat, and so may experience fewer parent-child attachment sequences, further reducing emotional contact with the parent.

Low eye contact and fear activation may both contribute to lower reinforcement of parental caregiving behaviors and hence lower sensitivity. There is some limited evidence for the link between temperamental fearlessness in infancy and CU traits. In a follow-up of approximately 7000 children to age 13 in the UK

Avon Longitudinal Study of Parents and Children (ALSPAC), females with conduct problems and CU traits (CP/CU) had been reported by parents as showing lower fear at age 2 than those with CP only (Barker *et al.*, 2011b). The interpretation is not however straightforward as the CP/CU group also had been less fearful in infancy than the CU traits only group. Boys in the CP/CU group had been reported as less responsive to punishment in infancy, but not as fearless.

Finally, early physiological under-arousal may contribute to risk for CU traits. Prospective associations between low pulse rate and disruptive and antisocial behavior problems have been replicated across many studies (Raine, 2002). This may reflect autonomic arousal which may in turn contribute to processes such as reduced fear conditioning. Several studies have found that reduced vagal reactivity, indexed by change of respiratory sinus arrhythmia to a stressor, is associated with increased disruptive behavior problems, consistent with an effect of autonomic under-arousal (Calkins *et al.*, 2007). The relationship between autonomic functioning and disruptive behavior problems is, however, complex. Disentangling the contributions of sympathetic and parasympathetic systems is not easy, and, consistent with the earlier review of context-dependent effects of physiological reactivity, may be environment-dependent (Obradovic *et al.*, 2010). Developmental studies from infancy to examine the specificity of physiological under-arousal to CU traits have not yet been conducted.

Adaptations to threat over development—from high reactivity to low reactivity

From Freud's early formulations of the child's attempts to cope with sexual abuse onwards, developmental theorists have understood children as actively regulating their emotional and physiological states to avoid high levels of distress and arousal, and to be able to act effectively in a range of social domains. This can, however, become problematic when a child is faced with chronic threat or maltreatment. As the temperament researchers Derryberry and Rothbart (1997) noted, under these conditions the child "may come to rely upon primarily avoidant strategies, disengaging attention from the threatening situation without attending to sources of relief and available coping options." From an information-processing perspective, the cost of an avoidant strategy may be that the child ceases to attend to the details of a threatening social encounter, or of other social experiences that to a greater or lesser extent resemble it. If the child's attention to the details is diminished, he/she is more likely to work from generalized inaccurate schemas, leading to a limited repertoire of social problem-solving options. Both psychodynamic and information-processing formulations envisage that this coping strategy is used to down-regulate negative emotions. This is likely to have implications for functioning in relationships and for the regulation of aggression. Where an avoidant strategy is used by the child, the negative emotions are not brought into the parent-child relationship, and hence the child is deprived of the experience, and does not practice

the skills, of regulating emotions within close relationships. Down-regulation of fear may inhibit anxious inhibition of antisocial or aggressive behaviors, and reduce fear conditioning. This hypothesis is consistent with the findings of Burgess *et al.* (2003) that the combination of fearlessness at 24 months and avoidant attachment at 14 months predicted behavior problems at 4 years. Avoidant strategies can be assessed in young children using story stem doll play procedures in which children are asked to respond to a range of interpersonal situations. Interpreting interpersonal processes as physical events (adopting the "physical stance") rather than as motivated by emotions, beliefs or desires (adopting the "intentional stance") is one way of avoiding the emotional implications of threat. In a longitudinal study of the children of women with postnatal depression, insecure attachment (mainly avoidant) predicted physical stance responses to a high threat doll play scenario, and this in turn was associated with teacher-reported behavior problems (Hill *et al.*, 2008).

Physiological reactivity to stress may also change over time. Findings that children exposed to major adversities commonly have evidence of increased HPA axis reactivity, while adolescents and adults often show hypoactivity, may be explained by "attenuation" of HPA activity over time (Trickett *et al.*, 2010). The resulting hypoactivity may then contribute to risk of disruptive behaviors via reduced physiological reactivity mediated via corticotrophin-releasing factor (Davies *et al.*, 2007). Overall the evidence linking HPA axis activity to disruptive behavior problems is inconsistent; however, a meta-analysis revealed an association with hyper-reactivity in preschool children, and with hypo activity in school-age children (Alink *et al.*, 2008), consistent with the attenuation hypothesis.

Peer influences

Peer influences are unlikely to be implicated in the earliest stages of the developmental pathways outlined thus far. However, it is well established that aggressive and oppositional children are commonly shunned by most other children, or associate mainly with other children with similar problems. They may therefore lack supportive or enjoyable peer interactions, and also run the risk of having their behaviors maintained or amplified through interactions with deviant peers. Furthermore, while overt behavior problems appear early, covert behaviors, such as stealing, appear later, and may be particularly susceptible to peer influences. There has been a long-standing debate over whether the poor peer relationships of disruptive children are solely a reflection of their problems, or whether they also contribute to them (Hill, 2002). Approaches to this question require prospective designs that examine whether peer processes add to the prediction of disruptive behavior problems after controlling for baseline problems. Several studies have failed to find effects of peer relationships on later antisocial outcomes after accounting for prior behavior problems and associated factors

such as family adversities (Tremblay *et al.*, 1995; Woodward & Fergusson, 1999). Recent prospective studies have, however, provided support for a role for peer influences when examining very specific processes, such as deviancy training (the amount of talk between peers about aggression, rule breaking, defiance of authority and property destruction), and the extent to which peers respond positively to such talk. Deviancy training in young school-age children has been associated with the persistence and increase of disruptive, and particularly covert, behaviors over up to 4 years (Snyder *et al.*, 2012).

Sex differences

A conceptual approach to childhood disruptive behaviors also has to attempt to account for their higher prevalence in boys than girls. In their comprehensive review of sex differences in the Dunedin Longitudinal Study, Moffitt and colleagues (Moffitt *et al.*, 2001) concluded that there was no evidence for differences in the *mechanisms* for behavior problems in males and females, and that the difference arose from a higher rate of developmental vulnerabilities in males. This then pushes the question back to: What is the nature of these vulnerabilities? Within the framework outlined earlier we are looking for possible deficits, for evolved variations that may confer risk or advantage depending on context, and for coping strategies. Males are often described as more vulnerable, with elevated rates of developmental disorders such as ADHD and autism cited in support. However that begs the question as to the type of causal process in play. It may be that there is a contribution of higher rates of deficits in males, with, for example, some evidence that the toxic effects of chemicals in utero on cognitive development are greater in males than in females (Horton *et al.*, 2012). Equally, many of the candidates for explaining sex differences are likely to be evolved differences with context-dependent advantages or risks. For example, low pulse rate, an index of under-arousal, is not only a robust predictor of violence in children and adults, it also shows sex differences. Males have a lower resting mean pulse rate than females and this difference is evident in young children, consistent with the early onset of persistent aggression (Raine, 2002). This difference may facilitate sex differences in aggression, seen in the general population, which is probably an evolved functional difference (Glover & Hill, 2012), that at the same time generates a larger number of males than females at the lower end of the normal distribution.

There may also be effects of sex-linked genes. One example is the MAOA gene, which is on the X chromosome. If, as is commonly found, heterozygous females show $G \times E$ patterns similar to the homozygous high activity variants (Hill *et al.*, 2013; Melas *et al.*, 2013), then more males than females are at risk for disruptive behavior problems in the presence of adverse or unsupportive environments.

It may be that mechanisms underpinning the male predominance for disruptive behavior in childhood also contribute

to the higher rate of affective disorders in females starting at puberty. The activity of the catechol-O-methyltransferase (COMT) gene, which encodes an enzyme that metabolizes catechol compounds, including dopamine, illustrates the point. COMT's enzyme activity, and the neurochemistry and behavior of COMT knockout mice, are both markedly sexually dimorphic (Tunbridge & Harrison, 2011). In a series of elegant studies Thapar and colleagues have shown that a high activity variant is associated with conduct disorder (CD) comorbid with ADHD, and this finding has been replicated by other investigators (Langley *et al.*, 2010). Whether or not there is a sex difference in the association between COMT and CD in ADHD is not known, but the high activity variant has been associated with lower IQ in boys but not in girls (Barnett *et al.*, 2008). By contrast, the high activity variant is associated, in Caucasians, with panic disorder in females but not in males (Domschke *et al.*, 2007). There are also marked differences between males and females in the rates of neurodevelopmental disorders; the reasons for this are discussed in Chapter 3.

"Comorbidity"

The co-occurrence of disruptive behavior problems with symptoms of apparently different disorders is very common. This is often referred to as "comorbidity"—a term that strictly speaking refers to the co-occurrence of distinct disorders. In this context, however, the term is a misnomer, as in many instances this is unlikely to be the explanation. Nevertheless, consideration of patterns of co-occurrence is central to the investigation of disruptive behavior problems.

As we argued earlier, attempts to build causal models of disruptive behavior problems will flounder either if the phenotype is too broad and heterogeneous, or if it is too narrow. If substantial commonalities could be shown between disruptive behavior problems and other childhood disorders, that could imply that there is a broader phenotype with common underlying mechanisms. We consider this possibility in relation to depressive disorders. Cross-sectionally, links between disruptive and depressive disorders are found across childhood and adolescence, in representative as well as referred samples; a meta-analysis of early epidemiological findings reported a joint odds ratio of over 6, little lower than that for depression-anxiety overlaps (Angold *et al.*, 1999). The two sets of difficulties are also related developmentally: although some studies find that depression predicts disruptive behaviors, by far the most commonly reported sequence is one whereby CD/ODD precedes, and predicts to, subsequent depression. In most early diagnostically-based studies, groups meeting criteria for both CD and ODD were combined. More recently, investigators have begun to examine predictions from these two disorders separately, and found that ODD emerged as the more salient precursor (see e.g., Copeland *et al.*, 2009). It is possible therefore that oppositional defiant and depressive symptoms

are manifestations of the same underlying processes. Some of these processes could lie in shared risk exposures. Psychosocial risks for both conduct problems and depression are legion, and undoubtedly overlap; in one study, more than two-thirds of the shared variance between co-occurring conduct disorder and depression in adolescence was attributable to shared risk factors (Fergusson *et al.*, 1996). Shared temperamental features and genetic risks also seem likely to be implicated. Genetically informative studies have pointed to shared genetic and environmental contributions to CD-depression overlaps (see e.g., Subbarao *et al.*, 2008). In addition, investigators are beginning to explore whether effects may be mediated by shared dispositional factors such as negative emotionality (Tackett *et al.*, 2011), or symptoms such as irritable mood (see Chapter 5). As noted above, some studies have found that it is ODD, rather than CD, that presents the stronger risk for subsequent depression. Recent studies have also shown that ODD symptoms include two closely related but separable dimensions: a “headstrong” dimension, related to current and future antisocial behaviors, and an “irritable” dimension, associated with risk for depression. Initial evidence from twin studies suggests that the association between irritability and depression is largely attributable to shared genetic risks (Stringaris *et al.*, 2012). Refining the phenotype may thus entail both narrowing down to specific aspects of disruptive behavior problems—in this case negative emotionality or anger-proneness—and broadening beyond their confines—in this case to depression.

Disruptive behavior problems are also comorbid with ADHD. As described earlier, the high activity variant of the COMT SNP Val158Met is associated with conduct problems among children with ADHD, but not in those without (Langley *et al.*, 2010). This suggests a highly specific developmental pathway, implicating risks for ADHD combined with very specific mechanisms for this subgroup of children with disruptive behavior problems. Promising findings suggest possible mediation between the COMT variant and conduct problems in ADHD by limitations in social understanding (Langley *et al.*, 2010). Thus in this case the identification of a distinctive comorbid subgroup has refined the mapping of heterogeneity in the disruptive domain.

Comorbidity may also arise in other ways that illuminate developmental processes. We return here to the example of depression, where disruptive behaviors may increase risk through repeated experiences of failure at school, in relationships and in other contexts (see e.g., Capaldi, 1992). Associations of this kind have been widely reported, and appear to begin quite early in development; in one study, for example, externalizing problems were associated with increased exposure to stressful life events from early childhood onwards, contributing not only to the persistence of behavioral difficulties but also to increased risk for internalizing problems in both childhood and the teens (Timmermans *et al.*, 2010). Given the widespread impact of disruptive behaviors on family and peer relationships, and on school functioning, “developmental cascades” of this kind may be especially important in the disruptive

domain, increasing children’s vulnerability to associated problems, and also functioning to stabilize underlying behavioral difficulties.

Adolescent onset of disruptive and antisocial behaviors

As we have seen, aggressive and disruptive behaviors are evident from very early in development. Other indicators of antisocial tendencies—most notably, crime and delinquency—follow a quite different developmental course. Across time and cultures, these behaviors show a highly predictable pattern, rising sharply across the teens, then falling back equally clearly in the early adult years. This near-universal phenomenon—the age-crime curve of criminological theory—suggests that new processes relevant to the expression of antisocial tendencies come on stream in adolescence; it may also point to additional sources of heterogeneity.

Building on these observations, Moffitt (1993) proposed a developmental taxonomy whereby the overall “pool” of antisocial young people is made up of two groups, distinguished by age at onset, and differing in both etiology and course. The first, onsetting in childhood, has much in common with the groups discussed thus far, with roots in biologically-based individual differences in temperament and neuropsychological functioning, interacting and transacting with adverse pre- and post natal environments to give rise to early onset behavior problems. The second, emerging in adolescence, owes less to such individual vulnerabilities; instead, Moffitt (1993) argued that the teenage rise in antisocial behavior emerges alongside puberty and is prompted by frustrations attendant on the adolescent maturity gap, cultural and historical contexts influencing adolescence, and social mimicry of behaviorally deviant peers. In relation to longer-term outcomes, Moffitt posited that early onset conduct problems would result in life-course persistent antisocial behavior, while adolescent onset conduct problems would follow a more time-limited course.

In statistical terms, a model of this kind is ideally suited to testing via latent trajectory modeling. A recent review (Jennings & Reingle, 2012) identified over 100 studies using this approach to describe the number and shape of trajectories of violent, aggressive and delinquent behaviors. Despite variability in findings, the authors concluded that results were largely consistent with Moffitt’s taxonomy. Over time, however, two relatively well-supported qualifications to the original formulation have emerged. First, as outlined earlier, studies using broad-brush measures of conduct problems have confirmed that by no means all early onset conduct problems persist; indeed, though many children with early onset difficulties do show poor long-term outcomes, a “childhood limited” trajectory has also been detected in numerous studies of this kind. Second, adolescent onset problems have emerged as less transient than first assumed (Odgers *et al.*, 2008). Moffitt’s initial discussion noted

that adolescent delinquency can result in “snares” such as poor school achievement or substance use that may act to perpetuate antisocial life-styles; subsequent evidence suggests that, for some young people at least, processes of this kind undoubtedly do occur (Hussong *et al.*, 2004).

Many of the etiological factors argued to underlie early onset and persistent conduct problems are, as we have seen, extensively supported by research in childhood samples. Testing for “adolescent-specific” risks is more complex and would ideally require longer-term studies tracking samples prospectively from childhood to the adolescent years. Genetically-informative studies are now beginning to provide evidence of this kind; one recent study found that the genetic factors influencing externalizing behaviors in late childhood still influenced variability in early adulthood, but that new genetic and environmental influences emerged in adolescence (Wichers *et al.*, 2012). Findings from neuroimaging studies are still limited, and predominantly cross-sectional; here, however, current evidence is less consistent with a developmental account, with similar abnormalities in brain structure reported in both early and adolescent onset Conduct Disorder groups (see e.g., Fairchild *et al.*, 2011).

What is now clear, however, is that the onset of puberty is associated with the initiation of a range of neurobiological changes that are likely to be relevant to the overall rise in antisocial behavior in the teens. Much of this research has been designed to explicate the underpinnings of a broader category of risk-taking and the reasons why, across a range of contexts, adolescents appear to take “risky” decisions (Blakemore & Robbins, 2012). Neuroimaging studies have highlighted two features of particular importance here. First, the brain regions involved in cognitive control (including the prefrontal cortex) show protracted structural development that continues throughout adolescence and into early adulthood. At the same time, however, there appear to be heightened brain responses to socially relevant, reward-related cues that are adolescence-specific, prompted by the hormonal changes of puberty (Peper & Dahl, 2013).

In evolutionary terms, such heightened sensitivity to social stimuli should have adaptive advantages, preparing adolescents to meet the new social demands of the adult world. In some contexts, however, it may prove more problematic. Experimental studies have shown, for example, that adolescents are markedly more susceptible to peer influence in risky situations than are adults (Gardner & Steinberg, 2005), suggesting that the presence of peers “primes” motivations to more immediately available, albeit risky, rewards. As much adolescent delinquency is committed in peer contexts, the implications of such findings for antisocial behavior are clear. Peer influences (along with other social-contextual factors) have also been found to moderate hormone-behavior associations in the teens, with evidence, for example, that high testosterone levels are associated with nonaggressive conduct problems in boys with deviant peers, but with indicators of prosocial leadership in those with more conventional friends (Rowe *et al.*, 2004). Finally, early timing of puberty is also associated with increased risk for antisocial

behavior in the teens (Mendle *et al.*, 2007; Mendle & Ferrero, 2010). The mechanisms underlying this association are less clear. Though biologically-based influences may be involved, commentators have also proposed a “maturation disparity” hypothesis (whereby the gap between early maturers’ physical and psychosocial development puts them at risk of adverse outcomes), or the possibility that pre-existing behavioral difficulties may be accentuated by the new social challenges of adolescence (Ge & Natsuaki, 2009).

Conclusions

Our understanding of disruptive behavior problems has come a long way since Lee Robins (1966) first showed how enduring and impairing they can be. Several key general population longitudinal studies have now provided more detail on how early they start, how they develop over time, and how they arise and are maintained by individual susceptibilities and environmental adversities. Other studies, mainly of clinical samples, have highlighted likely heterogeneity within the disruptive domain, with far-reaching implications for our understanding of early developmental origins. Currently, this is where the evidence becomes sparse. We have many sporadic indicators of the role of genotypic variations, neuroendocrine functioning, and social cognitive processes, in interaction with the child’s experiences, but these have not so far been integrated into a coherent model of developmental origins. The aim of this chapter has been threefold: to review what we do know, to highlight what we do not, and to provide indications of what an integrated model of the developmental origins of disruptive behavior problems might look like. This goes beyond the evidence—but that is necessary in framing research hypotheses, just as it is in clinical practice. Informative though it has proved, a broad characterization of disruptive behaviors is a relatively blunt instrument when attempting to formulate a treatment plan. Children and their families differ in many ways, and some respond to current treatment approaches and some do not. The task therefore is to identify differences within the disruptive domain that provide clues to distinctive origins and treatment needs. Developmental histories are the backbone of clinical approaches; a framework of the kind outlined in this chapter, albeit still under construction, can add specificity to the enquiry. This is relevant not only to the clinical formulation, but also to talking with parents and children in ways that convey an understanding of their particular patterns of behaviors and emotions.

CHAPTER 5

Emotion, emotion regulation and emotional disorders: conceptual issues for clinicians and neuroscientists

Argyris Stringaris

Department of Child and Adolescent Psychiatry, Institute of Psychiatry, Psychology and Neuroscience, King's College London, UK

Terms and definitions

The word emotion is used to describe a wide range of phenomena in humans and animals. Lay people use the term emotion to describe their own feelings or those they observe in others. Clinicians infer their patients' emotions by interviewing and observing them and they diagnose emotional disorders using such descriptive phenomenology. Scientists apply the term emotion to describe a range of phenomena including physiological responses to emotional stimuli, cognitive appraisal of feelings and the way people respond to rewards. As we will see, there is only partial overlap between the various usages of the term emotion, making it impossible to come up with a single satisfactory definition.

An imaginary experiment

The following thought experiment may help map out the various usages of the term emotion. Imagine a teenager with arachnophobia, who has agreed to participate in a large-scale experiment where he is presented with images of spiders. A clinician interviews the patient, cognitive and emotion scientists observe him, a machine monitors his heart rate, and he also has a brain scan, all during the presentation of the spider.

The clinician's approach: description and first-person account

The clinician will rate as an emotion any **valenced** reaction. In this case, the valence will be negative—the patient's unpleasant feelings upon seeing the spider. Similarly, the clinician observes her patient's facial expression, tone of voice, posture and overall communication. This outward display of emotion, the clinician may describe as the young person's affect, which in this case

is negative. The clinician will also easily recognize this as a particular **type of emotion**, namely fear, as opposed to anger or happiness. The teenager himself is likely to describe his **feeling** as fear and may describe its **intensity** as mild, moderate or strong. Similarly, the clinician will rate the **duration** of the response—for example, how long the fear persisted after the image of the spider was no longer on display. The clinician will also have to judge whether the negativity of the experience goes beyond the way the young person usually feels these days. For example, depressed patients will be in a long-lasting state of negative feelings, a **mood**, which could alter their experience of being presented with a spider.

Indeed, valence, type of emotion, intensity, frequency and duration are the building blocks of most interviews and questionnaires used in clinical psychiatry and these are also used to validate the outcomes of most neuroscience research.

A neuroscientist's approach: distinguishing emotions from feelings

This reliance on patients' accounts makes clinicians often use the terms emotion synonymously with **feelings**. However, neuroscientists would argue that emotional reactions can be present even when the patient has no conscious awareness of the emotion-eliciting stimulus. Based on previous findings (Wiens, 2006), they might re-design the experiment to present the spider photographs at such a fast rate that the patient would not know he had seen them. This would show that such subliminal presentation of spiders would make the patient respond as if he had consciously processed the picture. The subliminal presentation could also increase the patient's heart rate and increase neural activity in his amygdala, a brain area implicated in emotion processing. It is argued that because emotional events

are relevant to the survival of the organism, they are processed with priority over non-emotional stimuli (Wiens, 2006). Hence, the spider presentation here will lead to the following interconnected events: **biological responses** (such as the increase in heart rate and amygdala activation), **response tendencies** (the actions, such as fight or flight, that result from threat) and the brain states that detect such responses to produce **conscious experience** (Critchley *et al.*, 2004).

More from the neuroscientist: context, and interpretation versus reward and punishment

Other scientists (Barrett, 2011) focus on how **context** and **interpretation** influence the **core affect** and how this may lead to the experience of different emotions. In keeping with this, cognitive scientists would try to show that the way the teenager in this example labels emotion will depend on context; for example, Was he there on his own? Was the environment familiar? Similarly, they would try to show that the young person's **appraisal** of the experience could have an impact on the emotion that will result. Yet others will talk of emotions as **responses to rewards or punishers**. In this experiment, the spider is a stimulus that acts as a punisher, something the person will try to avoid (Rolls, 2007). The principles of this theory are relevant to behavior therapy of emotional disorders as we shall see later on.

More than one way of defining emotions

Each of these ways of defining emotions has its limitations. For example, clinicians rarely distinguish between an emotion—which is meant to be short-lived—and the longer lasting moods. We have also seen that reliance on feelings can miss out important non-conscious processing of emotions. Yet, relying on physiology alone would also be problematic. Increases in heart rate or cortisol are not specific to any emotion and amygdala activation also occurs when people are presented with novel stimuli (Lindquist *et al.*, 2012). Also, while cognitive appraisal and labelling are important, it is sometimes hard to see how they are different from any other nonemotion-related cognitive process. One solution would be to define emotion by combining all this information. However, this is not straightforward—as we shall see further on, there is at best only modest overlap between the various methods and conceptual approaches to emotions. It has even been suggested that new terms should be applied to some of these phenomena and that using the word emotion to describe all of them is confusing (Kagan, 2004). For the time being, it is probably best to resist reifying emotion—it is still a broad concept and it may be either too early or simply wrong to speak of it as if it had clearly-defined material underpinnings.

Basic emotions

In the example above, the psychiatrist refers to fear as a type of emotion and distinguishes it from other negative emotions such as sadness, mirroring the way she would distinguish between

anxiety and depressive disorders. Yet, many researchers challenge this common-sense distinction. In this section, I discuss some of the main findings in this area and their clinical implications.

The debate about basic emotions

Our language recognizes a number of different emotions such as anger, sadness and joy. Some authorities claim that a set of emotions exist that are natural kinds (Ekman *et al.*, 2011), but this claim has been disputed (Kagan, 2004). The basic emotion view has certain affinities (Barrett, 2011) with Darwin's project of identifying universal and innate expressions in animals. In Darwin's own words:

that the chief [emotional] expressive actions are now innate or inherited,—that is, have not been learnt by the individual,—is admitted by everyone. So little has learning or imitation to do with several of them that they are from the earliest days and throughout life quite beyond our control

(Darwin, 1872).

and

all the chief expressions exhibited by man are the same throughout the world. This fact is interesting as it affords a new argument in favor of the several races being descended from a single parent-stock ...

(Darwin, 1872).

Basic emotions are said to be characterized by distinctive universal signals (for example facial expressions), a distinctive physiology, distinctive subjective experience and the fact that they are present in humans as well as other primates (Ekman *et al.*, 2011). Typical examples according to these authors are **anger, disgust, fear, joy, surprise, and sadness**. However, this notion of basic emotion has been challenged. First, proponents of basic emotion disagree between themselves about how many basic emotions there are. Ortony and Turner (1990) shows that basic emotions range from 6 to 16 according to the author writing about them. Moreover, previous findings about specific relationships between physiological markers and emotions may have been incorrect. It appears that what physiology distinguishes may not be the emotion but the accompanying environmental contingencies: whether one can do something about a challenging situation or not (Frankenhaeuser, 1971). In addition, recent findings challenge the universality of basic emotions. For example, Jack *et al.* (2012) found that Caucasians living in Western countries but not East Asians distinguished between a set of basic emotions. The debate around a recent meta-analysis (Lench *et al.*, 2011) on basic emotions highlights some of the main questions. The authors examined four so-called basic emotions: happiness, sadness, anger and anxiety and found that they can be distinguished from each other with moderate effect sizes and are correlated with changes in behavioral experience and physiology. However, the effect sizes of the differences between emotions of the same valence were very small. A good

Figure 5.1 The findings of Lench *et al.*'s (2011) pairwise comparisons between emotions can be accounted for by differences in valence and arousal between emotions. Emotion categories are depicted in a circumplex structure based on their average degree of valence and arousal. Average effect sizes for each paired comparison are listed. The largest effect sizes occur for cross-valence comparisons, followed by cross-arousal comparisons. The smallest effect size observed is between anger and anxiety, emotions of the same valence and arousal. *Source:* Lindquist, *et al.* (2013). Reprinted with permission from the American Psychological Association.

example is the distinction between sadness and anger: the best differentiation between these two emotions was through subjective experience ($d = 0.38$, $p < 0.001$); however, neither cognition ($d = 0.12$, $p > 0.05$) nor behavior ($d = -0.18$, $p > 0.05$), nor physiology ($d = 0.19$, $p > 0.05$) distinguished between anger and sadness. In a critique of this meta-analysis, Lindquist *et al.* (2013) suggest that valence and arousal explain most of the differences observed between so-called basic emotions. As shown in Figure 5.1, the strongest effect sizes of the difference are between emotions that differ in valence.

Basic emotions and the brain

Proponents of basic emotion also suggest there are dedicated brain regions subserving each basic emotion. This locationist approach has also come under scrutiny. A recent meta-analysis of brain studies (Lindquist *et al.*, 2012) found little evidence that emotions can be consistently and specifically localized to particular brain areas. Instead, the authors interpreted the evidence as supporting a model according to which emotions emerge out of more basic psychological operations but are not specific to emotions (e.g., such as the detection of salience). The functions of the amygdala are an example that is said to support this view (Lindquist *et al.*, 2012): fear-inducing stimuli fall into a class of uncertain and salient stimuli, all of which can activate the amygdala (Lindquist *et al.*, 2012). However, this constructionist interpretation of emotion processing in the brain has itself come under scrutiny. First, there is at least some evidence for the locationist approach. Perhaps the most characteristic example from the Lindquist *et al.* meta-analysis (Lindquist *et al.*, 2012) is

that the left orbitofrontal cortex (OFC) seemed to be specific to instances of anger. However, brain correlates of anger were not restricted to the OFC but also involved areas of the prefrontal cortex. Second, this meta-analysis may be testing a model that is too simplistic. Current proponents of a locationist approach would propose the existence of a network for basic emotions in the brain rather than specific regions. Third, MRI might still be too crude a method to localize emotions. Experiments with primates show highly specialized subpopulations of neurons within sections of the OFC for the processing of olfactory stimuli (Rolls, 2007). Fourth, this meta-analysis ignores that humans commonly experience feelings that correspond to such discrete emotions. The adolescent in the introduction's imaginary experiment distinguishes between his feeling of fear when faced with the spider and his anger when pushed over in the football pit. It is an important task to explain the conscious experiences that distinguish between such feelings, even if these are not due to localized brain activity but rather interacting networks.

In the introduction, we mentioned that another approach to the young man's emotions was to consider them as states that are elicited by rewards and punishers, so-called instrumental reinforcers (Rolls, 2007). This view, posed by Edmund Rolls, distinguishes between emotions on the basis of whether rewards or punishers have been delivered or omitted.

Emotion regulation

Emotion regulation is defined in various different ways. A broad, yet concise definition is due to Ross Thompson and will provide a useful background for the rest of this chapter:

Emotion regulation consists of the extrinsic and intrinsic processes responsible for monitoring, evaluating, and modifying emotional reactions, especially their intensive and temporal features, to accomplish one's goals

(Thompson, 1994).

The regulation of emotions has concerned writers at least since the first word of Homer's *Iliad* was scribbled: 'Rage—Goddess, sing the rage of Peleus' son Achilles' (Homer, 1924) to start an account of how a demigod's uncontrolled emotions led to strife, death, and disaster (Harris, 2002). Given the uncertainties about how to define emotion it is no surprise that the compound derivatives 'emotion regulation' or 'emotion dysregulation' are also vaguely defined. Also, the word regulation can give rise to confusion. It is a naïve view that all negative emotion is a bad thing that ought to be regulated. Such a view ignores findings that children prone to negative affect may be more resilient under certain environmental circumstances (deVries, 1984). Similarly, it would ignore that even very intense sadness or fear may be adaptive. Also, regulating an emotion does not necessarily mean suppressing it—for example, sedation is

not the same thing as control. I shall return to the issues of boundaries between emotions and normality in the section on psychopathology below.

Distinctions between emotion and emotion regulation

It has been rightly said that emotions are themselves partly defined as a means of evaluating and modifying experience. This suggests that emotions act to regulate emotions in their own right (Cole *et al.*, 2004). For example, the teenager in the introduction's imaginary experiment may experience less fear if he were presented with pleasant emotional stimuli at the same time as he was presented with the spider images. Such an interaction between emotions could be automatic, rather than a deliberate act of regulation. This type of emotion regulation by emotion is rarely studied and therefore much less understood (Moll *et al.*, 2007). Another problem with the distinction between emotion and emotion regulation is methodological. Does the young man of our example in the introduction report intense fear because he has experienced a strong emotional reaction or because he has not been able to regulate his emotion? This challenge may be overcome with physiological measurement, particularly as neuroimaging assesses the temporal relationships between emotion reactions (indexed by limbic activation, see below) and top-down cortical control.

Heterogeneity of emotion regulation

For example, the way infants regulate their anger seems to work far less in regulating their fear responses (Buss *et al.*, 1998). Similarly, a therapist might give different advice to the adolescent in the introduction if his presenting problem were uncontrollable anger towards his schoolmates, rather than fear towards a spider.

Different forms of emotional regulation

A useful classification for developmental scientists is what distinguishes between **intrinsic** and **extrinsic** emotion regulation (Fox *et al.*, 2003). Intrinsic refers to the ability of a person to regulate one's own emotions and extrinsic is the regulation by others (e.g., one's friend).

One of the most influential ways of classifying emotion regulation is due to James Gross (Gross, 1998), which distinguishes between two major phases of emotion regulation: **antecedent focused** and **response focused**. The first of the antecedent-focused phases is **situation selection**. This refers to approaching or avoiding people, places or objects. In our example from the introduction, the teenager could effectively regulate his emotions by taking precautions to avoid spiders. The second of the antecedent-focused phases of emotion regulation is **situation modification**. The next stage, **attention deployment**, includes **distraction**, **concentration** and **rumination** (Gross, 1998). As we will see below, infants who are better able to distract themselves by shifting their gaze away from distressing stimuli, better regulate their emotion. Similarly, concentrating on pleasant tasks, such as playing a game, may

regulate emotions. Rumination on negative emotions or feelings can have negative emotional consequences (Nolen-Hoeksema *et al.*, 2008). **Cognitive change** refers to how people interpret an emotional experience and it includes cognitive appraisal of a situation. As we will see below, this focus on appraisal has been studied extensively in the emotion regulation literature and is central to cognitive and behavior treatment approaches. **Response modulation** is listed as the only instance of response-focused emotion regulation strategies in Gross's model (Gross, 1998). This is a very wide category and includes taking drugs to decrease physiological responses, as well as exercise and relaxation.

Notwithstanding its heuristic value, this model has a number of shortcomings. First, the boundaries between the phases of emotion regulation are not always clear; for example, cognitive change can involve situation selection and modification and also have attention re-deployment as a consequence. Second, the category of response modulation is quite wide and may obscure important differences between regulation processes as diverse as drug treatment or biofeedback. Third, many important physiological aspects of emotion regulation, such as sleep or food intake, do not fall neatly into any of these categories. Also, exposure and habituation are some of the best-known and clinically-relevant strategies of emotion regulation, which also do not fit well with these distinctions. Because of their relevance for research in practice, I discuss these separately here.

Emotion regulation through **exposure and habituation** involves the activation of a fear through exposure and habituation through successive exposure to such a fear-evoking stimuli (Foa *et al.*, 1986). Habituation simply refers to the decreased response after repeated application of the stimulus (Thompson *et al.*, 1966). The principle is best illustrated through its clinical application in exposure therapy, such as when the teenager of our introduction's example is repeatedly presented with images of the spider; however, it is likely that emotion regulation in everyday life—the warming up in social situations, the improvement of performance by 'facing one's fear'—rely on the same principles. The exposure and habituation experiments also make clear a more general principle relevant to emotion regulation, namely the often reciprocal **relationship between emotions, actions and the environment**. In our example from the introduction, the young man could simply run away—or, if more aggressive and presented with a real spider, he might simply kill it. This is consistent with the definition of emotions as response tendencies and their postulated role in evolution. It is also important, though, to recognize how actions themselves impact on emotions. It is the action of repeated exposure or of avoidance that regulates emotions in different ways.

Linked with the distinction between approach and withdrawal emotion processes is the emotion regulation concept proposed by Davidson (Davidson, 1998). There, distinctions are made between the threshold for emotional reactivity, the amplitude of the response, and two components of 'affective chronometry', namely rise time to peak and the recovery time

(Davidson, 1998). It appears that individual differences in asymmetric prefrontal activation—an electroencephalographic measure—predict differences in components of this emotion-processing system.

I will now discuss some of the mechanisms that may underlie these emotion regulation processes.

The brain in emotion regulation: the generator-regulator model

A distinction most commonly made in brain research on emotion regulation is between a bottom-up process and a top-down regulation. In this model, limbic areas—particularly the amygdala—are involved in **emotion generation and expression**. The amygdala is a phylogenetically old structure involved in learning of emotional associations (Cardinal *et al.*, 2002). If the adolescent in the introduction had suffered damage to his amygdalae, he would probably be unable to experience fear. The amygdala is reciprocally connected with areas of the frontal cortex, such as the medial and inferior prefrontal cortex (mPFC and iPFC respectively) and lateral OFC. These cortical areas are activated during forms of emotion **regulation** such as cognitive appraisal (Ochsner *et al.*, 2012). It has been shown that increases in neural activity in the mPFC, iPFC and OFC are correlated with decreases in neural activity in the amygdala (Banks *et al.*, 2007; Goldin *et al.*, 2008). In our imaginary experiment in the introduction, the young man's ability to decrease his fear would correlate with the cortical dampening of amygdala activity. Such a top-down model (Blackford *et al.*, 2012) based on anatomical connections between prefrontal cortical areas and the amygdala in primates is presented in Figure 5.2 (Ghashghaei *et al.* 2007). The regulation of emotion through this vertical integration is said to follow two related principles (Tucker *et al.*, 2000), namely (a) a hierarchical integration of inhibitory control, by which lower circuits are subordinated to more flexible higher networks; (b) by what is called encephalization, where higher, general-purpose brain networks take over functions formerly served by lower, restricted-action circuits (Tucker *et al.*, 2000).

The brain in emotion regulation: recognizing complexity

Brain findings of emotion regulation vary between studies for a number of reasons. A major source of heterogeneity relates to the strategy used in the research. Some forms of regulation such as dyadic regulation (e.g., that between mothers and children that we will discuss later), are difficult to test in a scanning environment and their underlying brain mechanisms remain unknown. However, there are several sources even within one strategy of regulation. In a recent review, Ochsner *et al.* (2012) show that different brain areas and hemispheres are recruited depending on whether a subject is asked to increase a positive emotion or decrease a negative emotion. Another source of heterogeneity relates to the strategy used for reappraisal: reinterpretation of events seems to involve brain regions involved in response selection and inhibition (in the ventrolateral prefrontal cortex,

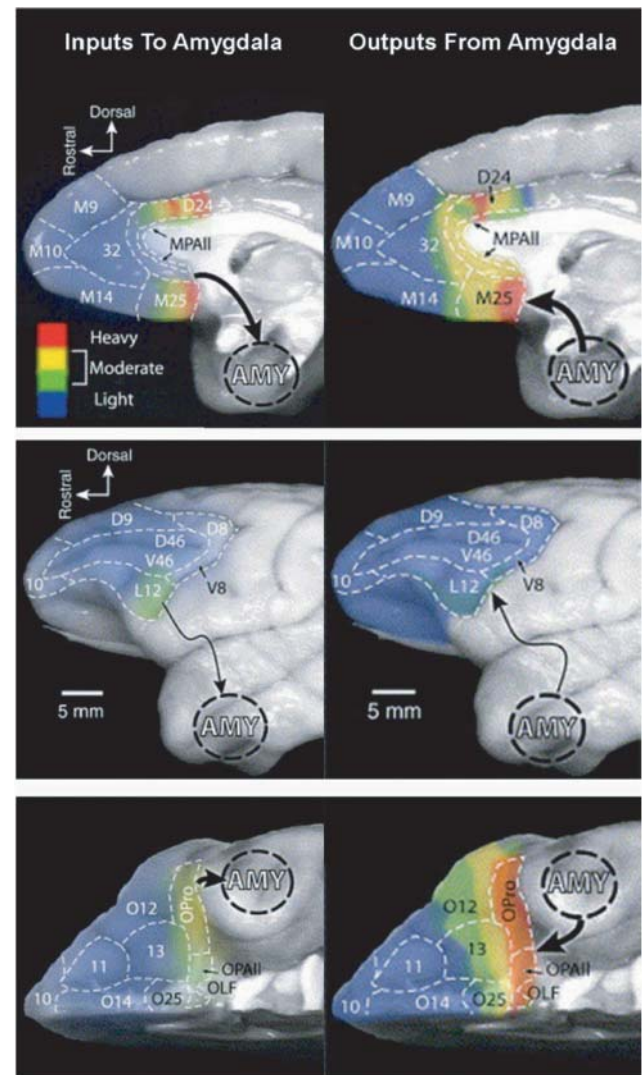

Figure 5.2 Distribution and density of output projections between the prefrontal cortex and the amygdala in the primate brain. Top row, medial aspect of the frontal lobe, middle row, lateral aspect of the frontal lobe, bottom row, orbitofrontal surface of the frontal lobe. AMY = amygdala. Source: Ghashghaei HT, Hilgetag CC, and Barbas H. (2007). Reprinted with permission from Elsevier.

vLPFC), whereas distancing recruits regions implicated in perspective taking, such as the parietal cortex (Ochsner *et al.*, 2012). Understanding these sources of heterogeneity is important also when appraising evidence from clinical neuroimaging studies. A recent meta-analysis of functional magnetic resonance imaging (fMRI) studies in depression found that emotional valence had a modulating effect on the comparison between patients and controls (Groenewold *et al.*, 2013). Depressed patients showed stronger activation in the right amygdala, left striatum, and anterior cingulate cortex (ACC) during negative processing; however, the same brain areas show less activation if depressed patients were processing positive stimuli. Also, certain forms of emotion regulation may not involve conscious top-down

regulation, but rely on a coordinated network of automated responses. On the basis of research in animals and humans, a brain network has been postulated that involves the striatum (particularly the ventral tegmental area, VTA) in perceiving the pleasure of a stimulus, the VTA and OFC in calculating the reward value of the object of that stimulus (such as food), and the ACC in determining the relative effort required in obtaining such an object (Der-Avakian *et al.*, 2012). As we will see below, such networks may be disrupted in depressive disorder and their restitution may be one of the effects of treatment.

The brain in emotion regulation: the importance of learning and timing

As mentioned in the previous section, exposure and habituation are important forms of emotion regulation. The model used most widely is that of fear conditioning, where what was a neutral stimulus is turned into a *conditioned* stimulus (CS) through pairing with an aversive stimulus (usually called the *unconditioned* stimulus). In our example from the introduction, it would involve presenting the spider paired with a smell or sound that would become the conditioned stimulus. Such conditioning requires the basolateral amygdala, as shown in studies with humans and animals (LeDoux, 2000). Exposure—which typically involves repeated presentation of the CS without the aversive stimulus—leads to extinction or habituation (Phelps *et al.*, 2000). Evidence in animals and humans shows that the mPFC is critical in extinction through its connections with the amygdala (Myers *et al.*, 2007; McNally, 2007). It appears that new protein synthesis is required for extinction in the mPFC, suggesting that this is a process involving **neural plasticity** (Myers *et al.*, 2007)—indeed, it has been suggested that extinction may be better thought of as new learning rather than unlearning (McNally, 2007). A recent interesting finding is that the timing of extinction treatment may determine whether a conditioned memory will be erased or only inhibited. In humans, fear conditioning is extinguished and does not return later in the same context if extinction treatment is done within minutes (as opposed to within hours) (Agren *et al.*, 2012).

Emotion and development

Interest in mechanisms of development has grown in parallel with research efforts in developmental psychopathology (Rutter *et al.*, 2006) and has highlighted challenges to developmental research in this area before appraising the existing evidence.

Emotion and development: challenges to its study

The first challenge concerns the **limits of reporting source** and descriptive phenomenology. Most of the research about mood and emotion in adults relies on self report. Indeed, self-reported emotional states are validating outcomes for most research studies—including imaging and genetics—in adolescence and

adults. However, research in newborns, infants, and young children has to rely on parent report or on observation. The correlation between different informants and methods is modest (Achenbach *et al.*, 1987). The use of different informants or different methods of assessment at different age groups limits our ability to judge the continuity of emotional states.

A related challenge is that some experimental paradigms are often **age-specific**. Some, for example the Still Face paradigm which we will discuss below, are particularly suited for early development. Another challenge concerns the technology used to study mood and emotion. For example, fMRI is hard to use in toddlers. Finally, as is the case for most of psychiatric research, it is unclear how best to map findings from different methods and sources onto each other. A particular challenge about research in early development is to map functional findings onto a **changing brain structure** (Giedd *et al.*, 1999).

With these caveats in mind, I will now discuss intra-individual change in emotions in early life, and then present two types of emotion regulation that are developmentally specific and finally discuss some of the challenges relating to transition periods in development.

Emotions and their differentiation in early life

Emotional expression becomes **richer and more differentiated** as children grow. One of the earliest models of emotional development is that of Banham Bridges (Bridges, 1932). It postulates that specific emotions develop from a rather ill-defined initial ‘excitement’ (Bridges, 1932). Stress and delight appear at 3 months, before the more refined emotions of fear, anger, disgust, distress, and excitement make their appearance. Indeed, studies find the references to feeling states increase as children grow older. A study by Dunn and colleagues (Dunn *et al.*, 1987) shows that the total number of children’s references to emotional states (primarily sleepiness, tiredness, hunger, pain, feeling hot or cold, sadness, happiness and pain) increases from 18 to 24 months of age. Studies also show that emotion comprehension improves with age. Pons, Harris and De Rosnay (Pons *et al.*, 2004) show that older children are overall better than younger children at emotion recognition, regulation and ambivalence.

Development and emotion regulation: some examples

Here I will use three examples to highlight influences of development on emotion regulation. One concerns parent–child interactions, the other interaction with peers, and the last one discusses internal capacity for attention allocation.

An important aspect of early emotion regulation is that it can be **dyadic** (in pairs), usually between parent and child, but also with other children or adults. A striking experiment demonstrating this is the Still Face paradigm developed by Tronick (1989). There, infant – mother pairs are observed through three phases: a baseline during which a mother is interacting normally with her child; a still face phase during which the mother follows the instructions to maintain an unresponsive face towards her

child; and a reunion phase during which the mother interacts normally again (Mesman *et al.*, 2009). Negative affect increases (with effect sizes around $d=0.5$) and positive affect decreases (with effect sizes over $d=0.9$) from baseline to the still face phase. During the reunion, positive affect increases dramatically ($d=0.75$) but negative affect carries over to the reunion phase ($d=0.04$). Maternal sensitivity is a significant predictor of the strength of positive affect in infants, while infant's positive affect is positively correlated with quality of attachment at age of one year (Mesman *et al.*, 2009). It also appears that mutual emotion regulation abilities between mother and child are significant predictors of later conduct problems in children: low levels of mutual positive emotion, emotion mismatching and high levels of mutual anger were more common in children with a chronic trajectory of emotional problems (Cole *et al.*, 2003). While these experiments demonstrate mutual emotion regulation in early development, they do not demonstrate causal effects. It remains unclear whether poor dyadic regulation is an indicator of genetically—influenced characteristics of one or both members of the dyad, and whether deficient dyadic regulation has a causal effect on emotion development in its own right.

Another major source of developmental effects on emotion is due to peer influences. The consequences of peer deviance and bullying on the development of behaviour problems are discussed in Chapter 26. Recent work suggests that bullying also has a major and possibly causal effect on the development of emotional problems (Arseneault *et al.*, 2010). Recent experimental work suggests that bullying may have an impact on the regulation of the physiological response to stress. In particular, compared to non-bullied children, those bullied show a blunted response of their hypothalamic-pituitary-adrenal (HPA) axis, as measured using cortisol, following a stress induction experiment (Ouellet-Morin *et al.*, 2011). See also Chapter 29.

Attention allocation is a mechanism that underlines emotion regulation that undergoes developmental changes. For example, when infants are distracted they also express less negative emotion (Harman *et al.*, 1997) and infants with longer attention spans are more likely to show signs of positive emotion (Putnam *et al.*, 2008). A brain indicator of early attention is a frontal negative EEG called the Nc—this is the earliest potential in human development that has been shown to relate to autonomic orientation of attention (Nelson *et al.*, 1996), and probably originates in the anterior cingulate. A recent study has shown that infants who are quicker to show the Nc (lower latencies) and show stronger Nc (higher amplitude) are better able to regulate emotions (Martinos *et al.*, 2012). In other words, infants low on self-regulation are slower to re-orientate attention.

Developmental transitions and emotions

As we have seen, emotional expression develops in childhood without any sharply-demarcated periods of radical change. Indeed, there are no periods that could be considered to be developmentally-sensitive, in the sense this term is being used

in, say, the development of human vision (Thapar *et al.*, 2009). However, a number of changes in emotional expression happen around the vaguely defined period of adolescence and these are worth discussing here.

Two of the most notable changes during adolescence are an **increase in impulsivity** and another is the increase in the **prevalence of depressive disorder** with the emergence of the **2:1 female-to-male** ratio in that disorder.

Impulsivity and emotions during adolescence

The term impulsivity is generally applied to describe a wide range of behaviors that increase during adolescence, including experimentation with alcohol and drugs, conduct problems, and unprotected sex (Casey *et al.*, 2010). It is unclear whether the same sort of impulsivity underlies each of these behaviors as it is unclear whether impulsivity should be seen as an emotional problem. However, the experimental paradigms used to study the possible mechanisms of impulsivity are related to emotion mechanisms as they both implicate reward-related processes. These show that adolescents are better than pre-adolescent children at cognitive tasks that involve response inhibition. However, adolescents find it more difficult to suppress responses to reward-related cues. Some authorities suggest that this increase in impulsivity during adolescence may be best explained by contrasting the curvilinear development of brain areas such as the nucleus accumbens to the linear development of the PFC (prefrontal cortex). For example, Casey and Jones (Casey *et al.*, 2010) challenge the view that behaviors characteristic of adolescence occur because the PFC is not mature enough for top-down control. Adolescence is said to be the time of maximal difference between the subcortical (e.g., nucleus accumbens) structures that mature earlier and the cortical (PFC) structures that only reach full maturity after adolescence (Casey *et al.*, 2010). According to the authors, an acknowledgement of the developmental imbalance between cortical and subcortical systems may provide new insights into the mechanisms mediating adolescent behaviors.

Transitions in emotional disorders

As discussed in Chapter 63, the prevalence of depression increases after puberty and the 2:1 female to male ratio in depression is established. The reasons for this gender difference are unclear and it is plausible that biological, social and cognitive factors interact to increase girls' vulnerability (Hyde *et al.*, 2008). Some of the most convincing evidence from Angold and colleagues (Angold *et al.*, 1999b) shows that pubertal girls with increased levels of sex steroids (testosterone and oestrogen) are more vulnerable to developing depression independently of the timing of pubertal changes or stress levels. The brain mechanisms through which hormones may exert their effects to increase risk for depression remain to be discovered (Blakemore *et al.*, 2006).

Disorders of emotion and emotion regulation: boundaries to normality, relation to basic science, and other challenges

Boundaries to normality

The boundaries between emotional disorder and normality are often unclear. Classification systems typically take the pragmatic approach of using cut-offs that would restrict the prevalence of a disorder to a relatively small proportion of the population. For example, for the recently-introduced category of *Disruptive Mood Dysregulation Disorder (DMDD)*, the criteria stipulate a relatively high *frequency* of temper outbursts as well as irritable mood of long *duration* alongside impairment due to these symptoms. These arbitrary thresholds have meant that the prevalence of DMDD is relatively low, at least in epidemiological samples, and that the associated impairment fits the description of ‘disruptive’ or ‘severe’ mood dysregulation. For practicing clinicians, contextual factors, such as the young persons’ and the parents’ ability to cope with emotional symptoms, are often taken into account before diagnosing. However, such judgements are often problematic as future negative consequences of symptoms are often independent of concurrent impairment (Stringaris *et al.*, 2013). Another approach is to consider whether the emotional reaction is proportional to the stimulus. A typical example is that of the boundaries between bereavement reaction and depression. Such decisions often involve an evaluative judgement about what constitute an appropriate reaction, though in the case of bereavement certain symptoms (e.g., suicidal ideation) are said to predict persistence of depression and impairment (American Psychiatric Association, 2013).

Overlap between basic science and clinical concepts

There are four principle methodological challenges when trying to translate the findings of emotion science to clinical concepts. The first concerns **duration** of the emotion response and the **eliciting object**: laboratory experiments of emotion processing typically focus on short-lived experiences lasting from milliseconds to a few minutes. It would be both ethically questionable and methodologically challenging to induce a long-lasting mood—sadness or irritability that lasts for days—in a laboratory setting. As a result, the brain mechanisms of enduring mood episodes are understudied. Indeed, understanding the difference between emotion and mood may be an important future goal. **Mood** is often defined by the absence of an emotion-eliciting object, such as when the amygdala is electrically stimulated in an animal or when patients are depressed for no apparent reason. It has been argued that mood may in that sense be different from emotion and unique (Rolls, 2007). The other distinction can be made on the basis of the associated **clusters of symptoms** and the heterogeneity within disorders. The adolescent of our imaginary experiment only suffered from a

simple phobia. However, clinical syndromes, such as depression, come with a number of other symptoms including anhedonia or low energy. These are hard to elicit and study in isolation. Another distinction can be made on the basis of **intensity** and associated **impairment**. The sadness experienced by patients is often excruciating and certainly impairing (Stringaris *et al.*, 2013), something that is also hard to model in an experimental setup. Finally, there may be other **qualitative distinctions**. It is not at all clear that elation for example—the hallmark of mania—is on the same dimension as ordinary happiness.

One symptom, many disorders

One problem is due to symptoms occurring across different disorders. Irritability and anger are probably the most prominent examples. Emotion theorists would view anger as one of the basic emotions, yet in psychiatric terms anger and irritability are symptoms of both emotional and disruptive disorders. As can be seen in Table 5.1, the symptom of irritability appears in the criteria of at least six different child psychiatric disorders and crosses the boundaries between emotional and disruptive disorders. For nosology, the presence of the same symptom in various disorders can inflate their overlap. The confusion for clinicians is that a motivating behavior (anger) is classified according to its possible consequences—so an angry child has a high chance of being diagnosed with a disruptive behavior disorder (ODD), rather than with an emotional disorder. In this example, the mechanisms underlying anger may be different from those that predispose someone with anger to be antisocial.

Table 5.1 Irritability compared to other common symptoms of child psychiatric disorders.

	Irritability	Worry/ Fear	Sadness	Antisocial behavior
Sep Anx	–	+	–	–
SpPh	+	+	–	–
SoPh	+	+	–	–
PTSD	+	+	–	–
OCD	–	+	–	–
GAD	+	+	–	–
Panic disorder	–	+	–	–
Agoraphobia	–	+	–	–
MDD	+	–	+	–
ADHD	–	–	–	–
ODD	+	–	–	–
CD	–	–	–	+

Sep Anx	separation anxiety
SpPh	specific phobia
SoPh	social phobia
PTSD	post traumatic stress disorder
OCD	obsessive compulsive disorder
GAD	generalized anxiety disorder
MDD	major depressive disorder
ADHD	attention deficit/hyperactivity disorder
ODD	oppositional defiant disorder
CD	conduct disorder

Also, irritability or related symptoms such as mood lability occur with a high frequency in disorders that do not list these symptoms in their criteria (Stringaris *et al.*, 2009c). For example, impairing mood lability occurs at a high rate among children with ADHD (Stringaris *et al.*, 2009c, Taylor, 2009). It remains unclear whether this mood dysregulation is due to ADHD core symptoms, a yet-unrecognized symptom of ADHD, or the manifestation of a dimension of mood dysregulation that cuts across ADHD and other psychiatric disorders (Shaw *et al.*, 2014). Similar questions arise with mood dysregulation in autism spectrum disorders (ASD).

Overlap between emotional and disruptive disorders

Psychiatric disorders overlap considerably: in a study of the UK general population (Maughan *et al.*, 2004) over 10% of children and adolescents with a disruptive disorder had an emotional disorder. Second, emotional and conduct problems share antecedents. For example, temperamental emotionality is a predictor of both emotional and disruptive disorders and seems to be a particularly strong predictor of the comorbidity between the two (Stringaris *et al.*, 2010). Third, emotional and conduct disorders also show sequential comorbidity (Angold *et al.*, 1999a). Indeed, ODD (oppositional defiant disorder) may be one of the most common antecedents of later depression in clinic and community samples (Burke *et al.*, 2005; Copeland *et al.*, 2009). People attempting to explain this overlap between disruptive and emotional disorders have focused on the heterogeneity of oppositional behaviors. Stringaris & Goodman (Stringaris *et al.*, 2009b, d) suggested that oppositional symptoms are made up of three correlated dimensions of irritable, headstrong and hurtful behaviors. Irritability has been shown in various studies to be a relatively specific predictor of later depression and generalized anxiety in up to 20-year follow-up studies (Stringaris *et al.*, 2009a) and an independent predictor of suicidality in a 30-year follow-up (Pickles *et al.*, 2009). Moreover the distinction of irritability from other oppositional behaviors has been shown in various studies including studies outside Europe or the United States (Krieger *et al.*, 2013). This wide presence of irritability across psychopathology has given rise to two explanatory models that are not mutually exclusive. One holds that irritability may be a cross-cutting dimension in psychopathology, and the other that severe irritability should be classified as a distinct disorder, an approach adopted in the Disruptive Mood Dysregulation Disorder category that has been introduced by the DSM-5 (Leibenluft, 2011; Mikita *et al.*, 2013). Neuroscience research has been helpful in distinguishing between severe irritability and other conditions (notably bipolar disorder, see Chapter 62).

The specificity of emotional disorders

The validity of current distinctions between child psychiatric disorders, then, is questionable (Rutter, 2011). Genetic evidence (Lahey *et al.*, 2011) suggests that there are pleiotropic genetic

effects across all psychiatric disorders and that these can be split into two main groups of emotional and disruptive disorders (in their terminology, internalizing and externalizing). Within internalizing disorders, a great proportion of the genetic liability for depression is shared with early anxiety disorders and the personality traits of neuroticism (Kendler *et al.*, 2006). In twin studies, it appears that internalizing disorders have strong genetic overlap, as do externalizing disorders. This has led some researchers to suggest that distinctions between emotional disorders may be redundant and that classification should be reconfigured in accordance with genetic findings (Stringaris, 2013). However, this approach would ignore findings of specificity of some anxiety diagnoses (see Chapter 2). Family and longitudinal and experimental studies seem to distinguish between anxiety disorders such as social phobia and separation anxiety disorder (Pine, 2007). Overall, however, the strong genetic overlap in psychiatric disorders raises the question about what makes them phenotypically distinct. The answer given at the moment is that this may be due to specific environmental circumstances (Eley, 1997).

Understudied emotional symptoms

As a result of the so-called paediatric bipolar disorder (see Chapter 62), researchers have concentrated their efforts on clarifying the role of irritability and understanding the importance of short-lived episodes of mania-like symptoms. Yet, there is far less research into some of the core **mania-like symptoms**, such as euphoria and increases in energy and activity. As a result, several things remain unclear: first, we do not know the developmental origins of such symptoms; second, we do not know whether such symptoms are on a continuum with everyday happiness; third, it is unclear whether such symptoms may be related to aspects of superior adjustment as has been suggested in adults (MacCabe *et al.*, 2010) and more recently adolescents (Stringaris *et al.* 2014). We recently found that in the UK general population (Stringaris *et al.*, 2011), episodic, mania-like symptoms are endorsed by a substantial proportion of parents and children. These episodic symptoms of exuberance form a latent factor that is distinct from (yet correlated) with episodic symptoms of undercontrol (such as irritability and disinhibition). Moreover, it seems that such symptoms are not predictive of impairment or comorbid psychopathology, once symptoms of undercontrol have been adjusted for. It remains to be seen whether these symptoms bear any predictive value for future psychopathology in their own right.

Emotions and treatment

Treatments of individual emotional disorders are discussed in the relevant chapters. Here I focus upon two questions about treatment that follow from the discussions above. The first concerns specificity of treatments, the second, whether people's emotional responses influence treatment effects.

Boundaries of treatments and underlying mechanisms

We have seen that the distinctions between categories of emotions are disputed as are the boundaries between the different emotional disorders in psychiatric classification. It is therefore no surprise that treatments for emotional disorders are not specific to any particular condition. The broad term cognitive-behavioral therapy (CBT) is used to describe treatments that have shown to be modestly effective for both depressive and anxiety disorders (see Chapter 38). For example, in children with obsessive-compulsive disorder (OCD) exposure and response prevention treatment appears to be effective for OCD symptoms as well as for depressive symptoms and patient's temper outbursts (Krebs *et al.*, 2013). Similarly, serotonin re-uptake inhibitors (SRIs) are the first-line drugs used to treat emotional disorders, again with rather modest success. Do all these treatments act in the same non-specific way or are there important distinctions? Neuroscience may be helpful in answering these questions. Recent findings suggest that it may be useful to distinguish between cognitive-focused and more activation-focused CBT protocols. Both approaches (Cuijpers *et al.*, 2007; Wiles *et al.*, 2013) seem to be effective at least in adults with depression, yet they may differ in how they achieve this effect. Siegle (Siegle *et al.*, 2012) and his colleagues scanned depressed adults before and after 16–20 sessions of cognitive therapy. They found that patients with the lowest pre-treatment activity in subgenual anterior cingulate cortex (ACC) in response to negative words displayed the most improvement after cognitive therapy. This is particularly interesting given that (as noted earlier) the ACC is known to decrease activity in limbic regions—a top-down form of regulation as one might expect of cognitive therapy. The mechanisms of action of behavioral activation may differ to that of cognitive therapy. An fMRI study by Dichter *et al.* (2009) suggests that brain areas mediating responses to rewards including the orbitofrontal cortex were modulated by behavioral activation therapy.

Emotion and treatment effects

We have discussed above how a child's difficult temperament might be advantageous under difficult circumstances (deVries, 1984). In recent years, Belsky (Belsky *et al.*, 2009) has proposed that, with supportive parents, infants who score high on negative emotionality may have *better* outcomes than their peers scoring low on negative emotionality. This raises interesting questions about the effects of one's emotions on one's own treatment. It is interesting to examine whether personal characteristics influence response to treatment—put simply, are there patients who benefit in particular or are particularly harmed by certain treatments? Scott and O'Connor (Scott *et al.*, 2010) recently showed that among children with conduct and oppositional problems taking part in a randomized controlled trial, those scoring high on emotional dysregulation were more likely than the rest to respond to a parenting intervention. It has been claimed (Belsky *et al.*, 2009) that plasticity genes (such as 5-HTTLPR, a variant in the promoter region of the gene coding for the serotonin transporter (Uher *et al.*, 2010) may explain emotionality and its effects on treatment. Overall, however, the results for the effects of such

personal characteristics or of genetic prediction or moderation of treatment have been modest. For example, in the pharmacological treatment of depression, no reliable genetic predictor of treatment response to drug treatment has been found (although it does seem that treatment response is modestly influenced by genetic variation) (GENDEP, 2013). Similarly, more evidence is required to understand how genetic variants may influence the outcome of psychological treatments (Lester *et al.*, 2013).

Conclusion and outlook

I wrote this chapter to present the advances in knowledge about emotion and emotional disorders and take on confusing concepts and findings. Some of the problems in the field may be easily overcome if we become aware of the ambiguities and problematic definitions of the terms we use—this applies particularly to the word emotion itself. The same caution is warranted when extending terms used in basic science to clinical concepts and vice versa—as I have shown, a lot more work is needed to translate findings from one into the other. All the challenges discussed in this chapter also need to be tackled by empirical research. Developing new experimental paradigms of emotion regulation—for example to study the effects of activity on emotion—can yield important insights into mechanisms of treatment for emotional disorders. Other challenges will require improvements in technology—reliable longitudinal functional imaging studies that span critical periods of development is a particular example. Some of the most important challenges, such as understanding the relationship between short-lived emotions and the prolonged mood states that clinicians encounter in their patients will require a combination of research approaches and may warrant new terminology to accommodate their implications.

CHAPTER 6

Attachment: normal development, individual differences, and associations with experience

Mary Dozier¹ and Kristin Bernard²

²Department of Psychology, Stony Brook University, Stony Brook, NY, USA

According to John Bowlby (1969/1982), the attachment system evolved to enhance reproductive fitness. Infants develop attachments to figures who are “older and wiser” than themselves and seek to maintain proximity with these attachment figures under threatening conditions. The infant’s behavioral repertoire of crying, smiling, clinging and following represents an organized system, designed to maintain or restore proximity to the caregiver (Sroufe & Waters, 1977a, b; Bowlby, 1988). By the time the infant is capable of crawling or walking, the attachment system has developed fully such that the infant does not want to move far from the parent except when circumstances are familiar (Bretherton, 1985). Under conditions of threat, when proximity is especially important to survival, the need for proximity to the caregiver is intensified (Bowlby, 1969/1982; Rutter *et al.*, 2009). For example, when the infant is fearful of a stranger or a startling sound, the caregiver is sought out for protection, with the response intensified in proportion to the perceived threat. Given the basic evolutionary function of this system, attachments are expected to develop in virtually all ordinary childrearing conditions. Although the attachment system may have special significance for the infant, attachments are thought to remain important for humans throughout life.

Historical context of the development of attachment theory

Attachment theory was developed in response to psychoanalytic and social learning theories of the time, and in the context of observations of the pernicious effects of privation on human and non-human young, and a burgeoning literature on ethology and evolution. John Bowlby articulated what has come to be known as attachment theory. Mary Ainsworth played a critical role as an astute observer of individual differences in attachment, and

on the basis of these observations, in developing a system for classifying infants’ attachment quality.

Reaction to psychoanalytic theory

Bowlby was trained as a psychiatrist at a point in time when psychoanalytic thinking dominated the field. While training at the British Psychoanalytic Institute, Bowlby was supervised by Melanie Klein, who, along with many others of the time, believed that the young child’s inner fantasy played a much more formative role in development than interactions with his or her real mother. As such, Kleinian psychoanalysts almost entirely ignored the mother’s actual behavior in the treatment of young children’s emotional needs. This approach very much conflicted with Bowlby’s sense of the importance of a child’s real caregiving experiences.

Effects of deprivation

Observations of the challenges faced by children who experienced inadequate parental care pushed Bowlby from the base of psychoanalytic thinking. In his first empirical study, Bowlby (1944) documented 44 cases of adolescent thieves. Many of these children were characterized as “affectionless,” demonstrating an extreme lack of empathy for others. Through detailed interviews about these children and their histories of caregiving, Bowlby observed that maternal deprivation and separation early in life emerged as a common factor. When he compared these 44 thieves to a sample of emotionally disturbed children who did not steal, Bowlby found that the lack of an important attachment figure in early childhood indeed distinguished the groups.

James Robertson was hired by Bowlby to help him observe hospitalized and institutionalized children who experienced separations from their parents. Robertson carefully observed children at home before they were hospitalized and followed

them into the hospital and home again. Frustrated with his inability to convince professionals of the challenges faced by children undergoing separation, Robertson made the movie, “A Two-Year-Old Goes to Hospital.” This film, although initially challenged by many, focused awareness on the consequences for young children of separation from their parents (Robertson & Robertson, 1989; Ainsworth & Bowlby, 1991; Bretherton, 1992).

Bowlby chaired the World Health Organization (WHO) commission on the problems faced by homeless children following World War II and met Spitz (1945) and Goldfarb (1945) who had chronicled the sterility of much institutional care during this period. Ironically, in response to high illness and mortality rates, institutional staff often prescribed minimal contact between staff and children, between children, and certainly between parents and children. What was generally not recognized was that, rather than protecting them from disease, the sterile conditions were making children more vulnerable. In the WHO report, Bowlby (1951) pieced together the different conditions of neglect and deprivation, articulating the importance of the young child’s relationship with the parent.

There was much criticism of this early work, with the naturalistic studies of institutional care challenged as not representative, not rigorous, and certainly not experimental (Bowlby & Robertson, 1953; Ainsworth, 1962). Critical to the acceptance of this work were links to Harlow’s experimental findings of the effects of deprivation on infant rhesus macaques (Harlow, 1958). Finding that infant macaques became attached to the cloth diaper in their cage even when fed by a wire mesh device made a good case for contact comfort being separate and not driven by “oral needs” (as suggested by psychoanalytic theorists of the time) or reinforcement (as suggested by social learning theorists of the time). Bowlby understood the needs for attachment as deriving from an evolutionarily based system that served to organize responses toward a goal of maintaining proximity to the caregiver (Bowlby, 1969/1982).

Ethology and evolutionary theory

Bowlby was first struck with Lorenz’s (1957) findings that goslings became imprinted on their mothers. Lorenz had described goslings’ imprinting on the first moving object seen after birth. Usually the first moving object seen is the mother, such that the gosling typically follows the mother, with chances for survival enhanced as a result. Among goslings, this behavior is seen even though goslings are not dependent upon mothers for their food. Based upon these and other observations, Lorenz (1957), Tinbergen (1951), and others developed a theory of ethology, which represented an elaboration of Darwin’s theory of evolution. The behaviors described, such as imprinting, were seen as evolutionarily prepared, but dependent on the environmental conditions to elicit them. In nearly all ordinary contexts, the environment could be expected to provide the necessary conditions to elicit the behavioral repertoire.

The influence of ethology on Bowlby’s conceptualization was profound (Ainsworth & Bowlby, 1991). Ethology provided

a framework for thinking about how the behaviors of the young infant—crying, smiling, clinging, following—all represented early evolutionarily prepared behaviors infants displayed toward the caregiver. The attachment behavioral system, like the imprinting of the gosling, was seen to consist of evolutionarily prepared behaviors. These behaviors are neither instincts (i.e., emerging regardless of environment), nor do they represent secondary reinforcements as the result of pairing with food (i.e., as suggested by both social learning and psychoanalytic theories of the day [e.g., the gosling could feed itself, and the rhesus macaque became attached to cloth “mother”]). Although particular stimuli are needed to elicit such behaviors, an “ordinary” environment would indeed elicit them. Only an environment falling outside that which would promote survival of young (i.e., no mother present) would fail to elicit. Importantly, the behaviors are organized around promoting survival of the individual’s genes (Bowlby, 1969/1982). In the case of the gosling and the human, as well as many other mammals, these behaviors are organized around maintaining proximity to caregiver, a goal that enhances survival of the genes.

Ainsworth as methodologist

Mary Ainsworth came to work with Bowlby at the Tavistock Clinic in 1950. As a student, she had worked with William Blatz (1966), who was a proponent of “security theory,” (i.e., the theory that children derive security from their parents). Thus, even before working with Bowlby, Ainsworth had come to see parents as providing a secure base for children. In her earliest work with Bowlby, she was responsible for analyzing data from the institutionalized children collected by Robertson. Robertson’s intensive observations of the families and children in their natural environments motivated Ainsworth to engage in similarly rich observations in her future work. In 1958, Ainsworth left the Tavistock Clinic for Uganda. With minimal funding, Ainsworth began a study that followed 28 Ganda babies and their 23 families over the first year of life (Ainsworth, 1967). During this period, she carefully observed precursors of attachment behaviors, and attachment behaviors. Ainsworth recognized that the organization of the attachment behaviors was the means by which the attachment develops.

Some years following her Ugandan study, Ainsworth initiated a second observational study, following 26 families in Baltimore, each of which consisted of two middle-class parents and their newborn infant, observing for at least 70 hours in each home throughout the first year of the infant’s life. Close to the child’s first birthday, parents brought their children in for a laboratory assessment. It is this laboratory assessment of attachment that is among Ainsworth’s key legacies. Although previous work had involved extensive hours of observation, she developed a laboratory assessment of attachment that could be conducted in less than 25 minutes. The assessment, the Strange Situation, is a series of separations and reunions between parent and child that provide a compelling context for observing children’s behaviors toward the caregiver when distressed. She developed

this assessment originally to examine the balance of attachment behaviors and exploratory behaviors in a context of increasing stress (Ainsworth *et al.*, 1978).

Infant attachment quality

Measurement: the strange situation

The Strange Situation that Ainsworth developed has become the gold standard for assessing attachment quality among infants. The Strange Situation consists of eight episodes in which the child is separated from and then reunited with the parent twice (see Table 6.1 for overview of procedure). Of particular relevance for coding attachment is the child's behavior toward the parent during the reunion episodes. This behavior is thought to reflect the child's expectations of caregiver availability when distressed.

Whereas the *presence* of an attachment relationship is essentially universal (except under unusual conditions), there is variability in the *quality* of attachment relationships. Children's behavior during reunion episodes of the Strange Situation highlights these individual differences in attachment patterns (see Table 6.2). Children who turn directly to their parents to be soothed are classified as having secure attachments. Those who turn away are classified as having avoidant attachments. Children who show a combination of proximity seeking and resistance/anger toward the parent are classified as having resistant attachments. These three types of attachment, secure,

avoidant, and resistant, are considered organized attachments because they are thought to represent strategies that maximize caregiver availability (Main, 1990). More specifically, secure children are able to move directly to parents, confident that their bids for reassurance will not be rebuffed. Children with avoidant attachments turn away from parents who would rebuff more direct bids for reassurance. Children with resistant attachments are thought to have effective strategies for eliciting responses from inconsistently available parents. Thus, these patterns develop through repeated interactions between children and their parents during which children develop expectations of their parents' availability in times of distress.

For the first decade after Ainsworth *et al.* (1978) published the classification system, researchers used these three categories to classify children's attachment. About a decade later, Main and Solomon (1986, 1990) introduced disorganized attachment as a distinct category. Disorganized attachment was first identified because some children were difficult to classify and/or showed behaviors that fell outside of those characterized in Ainsworth *et al.*'s system. Indeed, about 15% of children in typical samples were difficult to classify using the original criteria for secure, avoidant, and resistant (Main & Solomon, 1986). Disorganized attachment represents a breakdown in attachment strategy, with children appearing to lack a solution for dealing with their distress (Main & Solomon, 1990). Children with disorganized attachment show odd or anomalous behaviors when distressed in their parents' company. Such children do such

Table 6.1 Strange situation overview.

Episode	Participants	Time (min)	Procedure
1	<ul style="list-style-type: none"> • Mother • Child • Researcher 	1	Researcher introduces mother and child to the room and reviews instructions
2	<ul style="list-style-type: none"> • Mother • Child 	3	Mother sits and child plays with toys. Mother can respond if child initiates interaction
3	<ul style="list-style-type: none"> • Mother • Child • Stranger 	3	Stranger enters room and sits quietly for 1 minute, talks to the mother for 1 minute, and engages with child for 1 minute
4	<ul style="list-style-type: none"> • Child • Stranger 	3 (shortened if child is too distressed)	Mother exits the room. Stranger responds to child as needed (picks up crying child, interacts minimally to non-distressed child)
5	<ul style="list-style-type: none"> • Mother • Child 	3	Mother returns and greets child as she normally would. Mother resumes minimal interaction when possible
6	<ul style="list-style-type: none"> • Child 	3 (shortened if child is too distressed)	Mother exits the room. Child is left alone
7	<ul style="list-style-type: none"> • Child • Stranger 	3 (shortened if child is too distressed)	Stranger returns and responds to the child as needed (picks up crying child, interacts minimally to non-distressed child)
8	<ul style="list-style-type: none"> • Mother • Child 	3	Mother returns, greets child, and responds as she normally would

Table 6.2 Overview of strange situation classifications.

SS classification	Percentage ^a (%)	Strange situation behavior	Assumed meaning of behavior
Organized Secure (B)	62	<ul style="list-style-type: none"> • Acknowledges parent's return upon reunion • Returns to play after soothed • May or may not cry during separation 	Confident in parent's availability due to history of sensitive care
Organized Insecure-Avoidant (A)	15	<ul style="list-style-type: none"> • Fails to acknowledge parent's return—may continue to play, or turn away • Less likely to cry during separation 	Not confident in parent's availability due to history of unresponsive or rejecting care
Organized Insecure-Resistant (C)	8	<ul style="list-style-type: none"> • Mixture of seeking and resisting contact; angry quality • Highly distressed • Difficult to soothe 	Not confident in parent's availability due to history of inconsistent care
Disorganized (D)	15	<ul style="list-style-type: none"> • Odd or anomalous behavior • Contradictory behaviors (e.g., crying while turning away) • Lack of organized strategy 	Dysregulated in presence of caregiver due to history of frightening or atypical care (e.g., maltreatment)

^aPercentages based on meta-analytic findings of middle-class, nonclinical groups in North America ($N = 2104$) from van IJzendoorn *et al.* (1999).

things as freeze or still for a period of time, show contradictory attachment tendencies (distress and avoidance) consecutively or simultaneously, or show apprehension of the parent.

Stability

Evidence for the stability of attachment over time has been mixed, with effect sizes ranging from small to large (e.g., Waters, 1978; Egeland & Farber, 1984; Bar-Haim *et al.*, 2000). Greater instability (e.g., move from secure attachment to insecure or disorganized attachment) has been found for children who experienced more meaningful changes in the family environment, such as changes in caregiving quality or major family events or transitions (Thompson *et al.*, 1982; Vondra *et al.*, 1999).

Cross-cultural

In a meta-analysis of the Strange Situation conducted in eight different countries, van IJzendoorn and Kroonenberg (1988) found that differences within cultures were typically greater than between cultures. However, there were some cross-cultural differences observed. Whereas secure classifications were modal in all countries, there was a greater preponderance of avoidant classifications in Western Europe and resistant classifications in Israel and Japan. Although cross-cultural differences in parenting norms (e.g., infants rarely being separated from mothers in Japan) may play a role in the differences in Strange Situation classification patterns (e.g., Miyake *et al.*, 1985), few studies have examined these questions empirically.

Alternative approaches to measurement

Waters and Deane (1985) developed a Q-sort method of rating attachment security based on observer ratings and on parent ratings in parents' homes. The Q-sort asks the observer to sort descriptors (e.g., "child clearly shows a pattern of using mother

as a base from which to explore," "child easily becomes angry at mother") into categories from most to least descriptive of the child, with a forced distribution of items. The resulting Q-sort is then correlated with a prototypical secure sort. Thus, rather than yielding attachment classifications similar to the Strange Situation, the resulting score places children on a secure/insecure continuum. Van IJzendoorn *et al.* (2004) found that the Attachment Q-sort had strong psychometric properties when observers (rather than parents) made the ratings, and spent long periods in the home (i.e., more than 3 hours) prior to making ratings. The Q-sort was moderately associated with attachment quality assessed in the Strange Situation ($r = 0.31$), and was predicted by parental security ($r = 0.39$). Advantages of the Q-sort over the Strange Situation are its ecological validity, and the use with a larger age range than the Strange Situation (van IJzendoorn *et al.*, 2004). Disadvantages include the extensive period of time required for observation, and the lack of assessment of attachment disorganization.

Individual differences

There are a number of factors that contribute to individual differences in the quality of parent-child attachments. We provide an overview of these predictors, beginning with the most proximal—parental behavior—and moving to more distal factors such as parent attachment state of mind, parent psychopathology, and environmental conditions (see Figure 6.1).

Parental behavior

Parental behavior is seen as the critical mechanism by which individual differences in attachment develop. Attachment theory suggests that children will develop secure attachments if

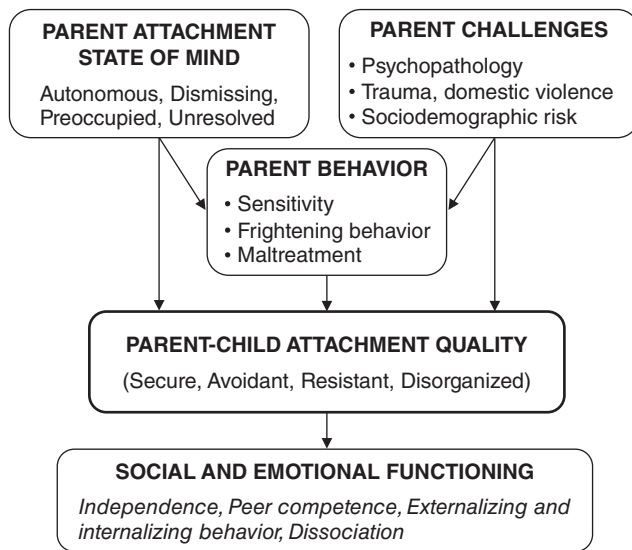

Figure 6.1 Conceptual overview of the predictors of individual differences in parent-child attachment quality and links to later outcomes.

parents are consistently available when they are distressed, and will develop insecure attachments when parents show other patterns of behavior. In her Baltimore study, Ainsworth and colleagues coded maternal behavior on four dimensions (which were highly intercorrelated): sensitivity, acceptance, cooperation, and physical and psychological accessibility. These dimensions strongly predicted infants' attachment classifications, with secure infants having mothers who scored high on all four dimensions (Ainsworth *et al.*, 1978).

Since Ainsworth's seminal work, parental sensitivity has been found to only moderately predict attachment security (De Wolff & van IJzendoorn, 1997). Although there is a range in the length of the observation period, no study of which we are aware has approached Ainsworth's intensive observation schedule. Differences in the context (e.g., play versus distress) may also contribute to the variability in findings. In addition, there are differences in what is defined as sensitive behavior. Recent attempts have been made to tease apart different components of sensitivity, such as responsiveness to children's signal in positive interactions (e.g., synchrony) versus sensitivity to children's cues of distress (McElwain & Booth-LaForce, 2006). Some have argued for a more narrow definition of attachment in which parental protection in the face of threat is the key to the child's sense of security, which most clearly aligns with Bowlby's original definition (Bowlby, 1969/1982; Goldberg *et al.*, 1999).

Odd, anomalous, and/or frightening behavior appears to have effects that are distinct from simply insensitive behaviors. Frightening or frightened parental behavior has been linked specifically to the development of disorganized attachment (Lyons-Ruth *et al.*, 1999; Schuengel *et al.*, 1999; Madigan *et al.*, 2006). Hesse and Main (2006) defined six scales of frightened or frightening (FR) parental behavior, including threatening (e.g., aggressive movements or postures), frightened

(e.g., backing away from distressed infant), dissociative (e.g., stilling, haunted tone of voice), timid/differential (e.g., submissive approach to infant), spousal/romantic (e.g., intimate touch), and disorganized (similar to infant disorganized behaviors). Maternal FR behavior has been linked to children's disorganized attachments (Abrams *et al.*, 2006). Infant attachment disorganization is also predicted by other extreme and atypical behaviors that increase infant arousal, such as negative-intrusive behavior, role confusion, and affective withdrawal (Lyons-Ruth *et al.*, 1999; Madigan *et al.*, 2006).

Not surprisingly, maltreatment is associated with heightened risk for disorganized attachment (Cicchetti *et al.*, 2006). Meta-analyses reveal large effect sizes between maltreatment and insecure and disorganized ($d = 2.10$ and 2.19 , respectively) attachments (Cyr *et al.*, 2010).

Attachment state of mind

Attachment state of mind refers to the way in which the parent, or the adult more generally, conceptualizes his or her own attachment experiences. Despite seeming to be less proximal than sensitivity, state of mind is the best-identified predictor of infant attachment (van IJzendoorn, 1995; Pederson *et al.*, 1998). Mary Main and her colleagues deliberately developed the system of assessing attachment state of mind to match children's attachment. That is, commonalities in conceptualizations among parents of children with secure attachments were identified, as were commonalities among parents of children with avoidant, resistant, and disorganized attachment. State of mind was assessed through an interview, the Adult Attachment Interview (AAI; George *et al.*, 1996). The interview asks adults to describe their parents, and to instantiate descriptions with particular examples. Interviewees are asked to recall times from childhood when they were hurt, upset, or rejected, and to think how their adult personality is affected by the way they were raised. Finally, incidences of abuse and loss are recalled. The semi-structured interview is transcribed and coded by reliable coders.

As a group, parents whose children were securely attached to them were called "autonomous" because they appeared able to evaluate attachment experiences freely. Characterizations of attachment figures matched well with specific descriptions for a rich, coherent picture, and attachment was valued. Parents whose children had avoidant attachments were called "dismissive of attachment" because they appeared to devalue attachment experiences. They typically showed a lack of memory with respect to attachment experiences and/or idealization of attachment figures. The parents of children with resistant attachments to them were termed "preoccupied with regard to attachment." These parents were caught up or enmeshed in attachment experiences, as shown by angry involvement and/or rambling discourse. Parents of children with disorganized attachments were most likely to be unresolved with regard to loss or abuse.

Beyond the initial sample of Main's in which the method ensured a good match between parent state of mind and infant attachment, the concordance has been very good.

Van IJzendoorn (1995) conducted a meta-analysis to examine the concordance between state of mind and infant attachment, and found a large combined effect size ($d = 1.06$) and high rate of correspondence (74%) for secure versus insecure concordance. Parent state of mind is moderately associated with parental sensitivity ($r = 0.34$, van IJzendoorn, 1995). Although it was anticipated that sensitivity would mediate the association between parent state of mind and infant attachment, the association between parent state of mind and infant attachment is stronger than the association between sensitivity and attachment, and sensitivity does not fully mediate the association between state of mind and infant attachment (Pederson *et al.*, 1998). It is possible that this is a measurement artifact, however, given that the AAI was developed to relate as closely as possible to infant attachment and/or because sensitivity becomes a less robust measure with shorter or fewer assessments.

Parent challenges

A number of factors can interfere with parents behaving in ways that foster secure attachments. When parents face significant challenges themselves, such as psychiatric disorders, extreme poverty, and their own unresolved issues regarding attachment experiences, it often becomes more difficult to consistently parent in sensitive ways.

Psychopathology

As would be expected, parents with psychiatric disorders, such as depression, borderline personality disorder, and substance abuse, experience particular challenges in parenting. Parental depression, for example, is associated with both withdrawn and intrusive parental behaviors (Goodman & Gotlib, 1999), which would suggest heightened risk for insecure attachments among children. Evidence linking maternal depression with infant attachment quality is mixed, with meta-analyses revealing a small, significant overall association between maternal depression and insecure attachment ($r = 0.18$; Atkinson *et al.*, 2000) and a non-significant association between maternal depression and infant disorganization ($r = 0.06$, $p = 0.06$; van IJzendoorn *et al.*, 1999). Mothers with borderline personality disorder are more likely to interact in intrusive ways and to have infants with disorganized attachments than control mothers without psychopathology (Hobson *et al.*, 2005). In addition to psychiatric disorders being associated with lower quality of parenting, psychiatric disorders are disproportionately associated with non-autonomous states of mind (as will be discussed in more detail later).

Trauma exposure and domestic violence

When parents experience unresolved trauma or domestic violence, it is often difficult for them to effectively buffer children. This failure can be the result of children witnessing violence involving attachment figures, or the result of parents

behaving in anomalous ways because of their own trauma experiences (Schuengel *et al.*, 1999). When parents are unresolved with regard to loss or trauma, they are susceptible to behaving with their children in frightening ways and children are at increased risk for disorganized attachments (Schuengel *et al.*, 1999).

Challenging environmental conditions

Living under harsh conditions can also interfere with optimal parenting and threaten the development of secure attachments. Cyr *et al.* (2010) conducted a meta-analysis of the effect of high-risk conditions on children's attachment. In comparison with samples of children from low-risk backgrounds, high-risk samples had higher proportions of insecure children and disorganized children ($d = 0.48$ and 0.48 , respectively). Furthermore, children who were not maltreated but had five or more socio-demographic risk indicators (e.g., low income, parental substance abuse, minority group, single parent, adolescent mother, and low parental education) had similar rates of disorganized attachment as maltreated children (Cyr *et al.*, 2010). Taken together, these studies suggest that adverse environmental conditions can contribute to higher rates of insecure and disorganized attachments.

Other factors: child care and child temperament

The National Institutes of Health in the United States invested enormous resources in assessing the effects of child care on children's development, with a particular focus on attachment relationships (NICHD, 1997). In this study of more than 1300 children, attendance at child care, the quality of child care, and the amount of child care was found to have no direct effects on attachment security. This was at odds with several previous studies (Clarke-Stewart, 1989; Belsky & Rovine, 1988) that had shown effects of the amount of child care on attachment quality. These findings were sustained in assessments of children at the age of 3 (NICHD, 2001).

There has been considerable debate about whether temperament and attachment are overlapping constructs. Temperament refers to individual differences in infant reactivity or regulation across attentional, behavioral, and emotional domains. In general, studies have not found strong evidence for an association between infant temperament and security of attachment (for a review, see Vaughn *et al.*, 2008). Although infant temperament does not determine the likelihood of having a secure or insecure attachment, several studies suggest that temperamental reactivity may influence the type of insecure attachment displayed. For example, infants with higher negative emotionality may be more prone to resistant patterns of insecurity (characterized by high levels of distress), whereas infants with lower negative emotionality may be more prone to avoidant patterns of insecurity (characterized by low levels of distress) (Belsky & Rovine, 1987; Marshall & Fox, 2005).

Links between infant attachment and later outcomes

Attachment quality is predictive of a number of important developmental outcomes, including independence in preschool, peer relations in middle childhood, and internalizing and externalizing behavior problems. Associations are typically stronger among children living in stable environments where conditions stay relatively constant over time than among children living in less stable environments (Weinfield *et al.*, 2000; Vondra *et al.*, 2001). Weinfield *et al.* (2000) have argued that continuity and discontinuity follow lawful patterns, with instability in care predicting discontinuity.

Several large longitudinal studies have studied attachment from infancy through adulthood, including the Minnesota Longitudinal Study (Sroufe *et al.*, 2005), the Bielefeld and Regensburg Projects (Grossman *et al.*, 2005), the London Parent-child Project (Steele & Steele, 2005), the Haifa Longitudinal Study (Sagi-Schwartz & Aviezer, 2005), the Berkeley Longitudinal Study (Main *et al.*, 2005), and the NICHD Study of Early Child Care and Youth Development (NICHD, 1997). The studies have provided both converging and diverging findings regarding how well attachment in infancy predicts subsequent outcomes. Additionally, a number of shorter-term studies that included assessments of attachment in infancy provide important data regarding the prediction of later outcomes.

Social relationships in childhood

Ainsworth (1969) and Bowlby (1969/1982) clearly distinguished attachment from dependency. Although children remain dependent upon their caregivers in a number of ways, secure attachment provides a secure base for exploration, theoretically allowing greater confidence in exploration (Sroufe *et al.*, 1983). Nonetheless, for a number of years, misunderstandings of the two constructs remained. For example, the behavior shown by avoidant children in the Strange Situation (i.e., appearing not to need their parents) led some to question whether, in fact, avoidant children were more independent than secure children. Sroufe *et al.* (1983) assessed this directly by examining preschoolers' dependence on their teachers through observed physical contact seeking and observed guidance, as well as through teacher ratings. Secure children were rated by teachers as more independent than avoidant and resistant children, and sought out contact and guidance less than avoidant and resistant children. These behaviors, although later in development, are in line with similarities observed between children with avoidant and resistant attachments in their home environments (Ainsworth *et al.*, 1978). Consistent with the original attachment theory tenets (Ainsworth, 1969; Bowlby, 1969/1982), these data support the idea that secure attachments in infancy support autonomous functioning in early childhood.

Consistent with these results, infant attachment classification at 15 months predicted social behavior at age 3, controlling for concurrent attachment classifications and maternal sensitivity (McElwain *et al.*, 2003). Specifically, resistant children were less assertive or controlling with a same-sex friend than avoidant children, and avoidant children demonstrated more instrumental aggression than secure and resistant children. Self-reports of social relationships in childhood also show associations with infant classifications. Children classified as resistant report higher loneliness in early childhood relative to children classified as secure (Berlin *et al.*, 1995). In a meta-analysis based on 63 studies, there was a small effect size for the overall association between attachment security and peer relations, $r = 0.20$ (Schneider *et al.*, 2001). Effect sizes were larger in studies of peer relations with close friends compared with peer relations with non-friends (e.g., classmates, acquaintances), and were larger in older childhood relative to early childhood.

Internalizing behavior

Two recent meta-analyses have found a small but significant effect for insecure attachment predicting internalizing behaviors (e.g., depressive symptoms, anxiety), with avoidant attachment most clearly driving the effect (Groh *et al.*, 2012; Madigan *et al.*, 2013). In their meta-analysis of 60 studies, Madigan *et al.* (2013) reported a small to medium effect size ($d = 0.37$) between insecure attachment and internalizing behavior in childhood (age of children across studies ranged from 18 months to 10 years). This effect was moderated by concurrent externalizing behavior, with higher ratings of externalizing behavior strengthening the association between insecure attachment and internalizing behavior. Additionally, studies relying on direct observations of internalizing problems demonstrated larger effect sizes ($d = 0.67$) than studies that used questionnaires, such as the CBCL ($d = 0.34$).

Externalizing behavior

Meta-analytic findings demonstrate that insecure, and most especially disorganized attachment is associated with externalizing behavior during childhood (Fearon *et al.*, 2010). Disorganized children appear most at risk for externalizing behaviors ($d = 0.34$), with smaller effects seen among avoidant ($d = 0.12$) and resistant children ($d = 0.11$). Groh *et al.* (2012) compared the effect sizes for attachment quality predicting externalizing versus internalizing symptoms. Both insecure and disorganized attachment predicted externalizing symptoms more strongly than internalizing symptoms, $d = 0.31$ versus $d = 0.15$ for effects of insecure attachment on externalizing versus internalizing symptoms, and $d = 0.34$ to $d = 0.08$ for effects of disorganized attachment on externalizing versus internalizing symptoms respectively (Groh *et al.*, 2010).

Dissociation

Disorganized attachment has been found to be predictive of later dissociative symptoms such as disruptions in memory and confusion of identity. Carlson (1998) found that disorganized attachment predicted teacher-reported dissociative symptoms in middle childhood and adolescence, and self-reported dissociative symptoms on the Schedule for Affective Disorders and Schizophrenia (K-SADS) at age 17 years and on a questionnaire at 19 years. The theoretical links between disorganized attachment and later dissociative symptoms are strong, but there are fewer empirical studies than with regard to externalizing or internalizing symptoms. Main and Hesse (1990) suggested that disorganized attachment reflects the infant's experiencing an unsolvable dilemma because the child is frightened of the parent from whom he or she must seek protection, resulting in a mini-dissociative episode that can be observed in the child's behavior in the Strange Situation.

Assessments of attachment beyond infancy

Although attachment to a caregiver has particular salience in infancy and early childhood, attachments remain important throughout life. Bowlby (1988) talked of the importance of attachment "from the cradle to the grave" (p. 62). The form that these attachments take changes across development, with children increasingly able to represent attachment figures internally over time (Main *et al.*, 2005).

Preschool

A preschool version of the Strange Situation was developed by Cassidy *et al.* (1992). This Strange Situation is similar to the infant Strange Situation, but with the stranger episodes eliminated under the assumption that strangers are not as threatening to preschoolers as they are to infants, and with longer separations sometimes used. Categories of attachment generally parallel infant categories. An exception is that controlling behavior is seen to a greater extent than disorganized behavior and is considered the outgrowth of disorganized attachment. That is, children become controlling of parents as a way to cope with feelings of disorganization (Main & Cassidy, 1988). The preschool Strange Situation has been used much less than the infant Strange Situation, and with generally less robust effects. Moss and colleagues have published the strongest findings with the preschool Strange Situation, showing moderate stability over time (Moss *et al.*, 2005).

Move to the level of representation

In infancy, the organization of the child's behavioral system is the essence of attachment, with measurement of attachment based on behavioral observations (e.g., Ainsworth, 1967). Even in infancy, though, these behaviors reflect the child's expectations of the parent's availability, and hence representations of attachment figures. Increasingly, the "move to the level of

representation" becomes more pronounced (Main *et al.*, 2005). With time, it is thought that children develop internal working models of self and caregivers based on their experiences of attachment-relevant events (Bowlby 1969/1982; Bretherton, 1992), with these internal working models providing rules that guide behavior, organize attention, and permit or limit access to memory (Main *et al.*, 1985). A number of measures have been developed to assess attachment at the level of representation in childhood and adulthood.

Story stems and narratives

Semi-projective measures have been used with young children to assess their attachment representations, such as the Separation Anxiety Test (Main *et al.*, 1985) and the Attachment Story Completion Task (Bretherton *et al.*, 1990). In the Separation Anxiety Test, children are asked how they would feel and what they would do in response to a range of separation scenarios (e.g., parents leaving for 2 weeks); in the Attachment Story Completion Task, children are asked to describe "what happens next" in a series of story stems (e.g., a child getting hurt). Coding of children's responses has taken several forms, with some paralleling the Ainsworth classification system, and others defining broader scales of security or related constructs. Although more work is needed to validate these measures with behavioral observations of children's attachment behavior, these representational measures relate to children's behavior in separation paradigms (e.g., Slough & Greenberg, 1990) and predict children's socioemotional functioning (e.g., Easterbrooks & Abeles, 2000).

Child attachment interview

The Child Attachment Interview (Target *et al.*, 2003) is an interview for children and adolescents modeled on the Adult Attachment Interview. Like the AAI, the Child Attachment Interview asks children to generate adjectives to describe parents and to instantiate those adjectives, as well as describe incidents of distress, among other things. Scott *et al.* (2011) found that attachment representations were related to observed parenting behaviors, and made distinct contributions to predictions of behavior problems. Further, children appear able to modify their narratives and presumably their representations when caregiving changes (Joseph *et al.*, 2014).

Adult attachment interview

The Adult Attachment Interview (AAI; George *et al.*, 1996), described earlier in this chapter, is the assessment of attachment state of mind used among adolescents and adults. As predicted by theory, attachment state of mind is associated with relations with peers and parents in adolescence (Allen *et al.*, 2003), and with adult functioning in romantic relationships (Bouthillier *et al.*, 2002). For example, partners' AAI classifications predict proactive emotion regulation during a problem-solving discussion (Bouthillier *et al.*, 2002), and psychophysiological activity during conflict discussions (Roisman, 2007).

Adults with serious psychiatric disorders are disproportionately characterized by non-autonomous states of mind (for a review, see Dozier *et al.*, 2008). Some psychiatric disorders are associated with dismissing state of mind (i.e., characterized by idealizing of attachment figures and/or lack of memory), whereas others are associated with preoccupied state of mind (i.e., characterized by angry involvement and/or rambling discourse). More specifically, disorders involving an externalizing focus such as antisocial personality disorder are often associated with a dismissing state of mind, and disorders that involve more self-focus such as borderline personality disorder are often associated with preoccupied state of mind (e.g., Fonagy *et al.*, 1996). Nonetheless, as Rutter *et al.* (2009) emphasize, attachment state of mind does not provide an explanation for the disorder in any of these cases.

Self-report assessments

Self-report assessments of attachment have been used extensively and many types of self-report assessments have been developed. Self-reports are very easy to administer relative to the Adult Attachment Interview, but relate weakly or not at all to Adult Attachment Interview assessments (Roisman *et al.*, 2007). In a meta-analysis, Roisman *et al.* (2007) found that the AAI was very weakly related to attachment style (mean $r = 0.09$). Nonetheless, the instruments often relate to variables of interest in meaningful ways (Roisman *et al.*, 2007).

Attachment and neurobiology

Non-human primate and rodent studies have provided compelling evidence for the effects of maternal care on the developing infant's neurobiology. Hofer (1994) has argued that specific maternal behaviors or processes serve as "hidden regulators" for the infant. The mother helps the infant regulate temperature, heart rate, and glucocorticoid production, for example. Hofer suggested that behavioral-sensorimotor processes, involving aspects of mother–infant attunement and synchrony, appeared particularly important to behavioral and neurobiological regulation. Not surprisingly, then, children show different physiological responses depending on caregiving quality and attachment quality.

Avoidance in the strange situation

In the Strange Situation, the apparent indifference shown by avoidant children in reunions with their parents belies their underlying anxiety about parental availability (Ainsworth *et al.*, 1978). These children often turn away from their parents, appearing to distract themselves with toys. If they are effectively distracted, as suggested by their behavior, their heart rates should decelerate; if on the other hand, they are avoiding contact with the parent and only appearing to be distracted by the toys, their heart rates should stay constant or even

accelerate. Indeed, Sroufe and Waters (1977a, b) found that children showed increased heart rate regardless of attachment classification, supporting the idea that avoidant children are not effectively engaged with the toys.

Avoidance in the adult attachment interview

Adolescents and adults with dismissive states of mind minimize the importance of attachment-related experiences, indicating that they cannot recall times in their childhood when they were hurt or rejected or denying that these experiences have an impact on their development. If these individuals are truly unaffected about such issues, their skin conductance (i.e., the amount they sweated) should not increase when queried; if however, they are actively avoiding issues, their skin conductance should increase. Paralleling the Sroufe and Waters (1977a, b) findings showing increased heart rate in avoidant children, young North American adults with dismissive attachments showed increases in skin conductance when asked about being rejected, upset, and hurt as children (Dozier & Kobak, 1992).

Cortisol reactivity in the strange situation

The Strange Situation is designed to be stressful to all children. However, Gunnar *et al.* (2006) have argued that, in the presence of supportive caregivers, most young children do not show a cortisol response under ordinary stressful conditions. This buffering function is important in protecting the developing brain from high levels of circulating glucocorticoids. Indeed, children with secure attachments to their parents have not shown increases in cortisol in the Strange Situation in three studies (Spangler & Grossmann, 1993; Bernard *et al.*, 2010); only children with disorganized and/or insecure attachment showed increases in cortisol. These results point to the importance of attachment in helping children to regulate physiologically as well as behaviorally.

Attachment among fathers

Increasing attention has been paid to the role that fathers play in children's development and to father–child attachment relationships (Lamb & Lewis, 2004). The association between paternal sensitivity and infant–father attachment security is weaker than the association between maternal sensitivity and infant–mother attachment security (for meta-analysis, see van IJzendoorn & de Wolff, 1997). As would be predicted given that attachment is considered to be relationship-specific (Sroufe, 1985), infants' attachment to fathers and to mothers is relatively orthogonal. Van IJzendoorn and de Wolff (1997) found only a modest association between infants' attachment to mothers and fathers. Fathers' state of mind is less predictive of infants' attachments to their fathers than mothers' state of mind is to infants' attachments to their mothers (van IJzendoorn, 1995).

Attachment among atypical populations

Attachment among children in foster care

Children in foster care experience disruptions in care at a point when developing and maintaining attachments is a key developmental task. Stovall-McClough and Dozier (2004) studied the development of children's attachment behaviors in their new homes over time. They found that after about 12 months of age, children required a substantial period of time before they appeared to show consistent attachment behaviors and/or to develop a secure relationship. Ultimately, though, foster children placed with autonomous foster parents usually developed secure attachments (Dozier *et al.*, 2001), whereas children placed with foster parents with non-autonomous states of mind usually developed disorganized attachments. Consistent with Bowlby's (1951) observations, disruptions in care are problematic for children, but the quality of surrogate care is important in how they adapt.

Attachment in kibbutz

Kibbutz conditions likely represent the most benign group care conditions possible. Sleep-away kibbutzim existed in Israel for much of the 20th century (Aviezer *et al.*, 2002), with the model driven by an ideological belief in collective living and by practical needs. Care for children was excellent in terms of resources, activities, and time with caregivers other than the parents. Time with parents was limited, and most especially, children slept in groups away from their parents. In two studies, children reared in sleep-away kibbutz showed lower rates of security than seen among usual low-risk children. Sagi *et al.* (1994) found that 48% of children in communally sleeping conditions developed secure attachments, compared with 80% of children in family-based sleeping arrangements.

Attachment and interventions

Infants and toddlers

There are several attachment-based interventions for parents of infants and young children with emerging evidence bases. The interventions range from those that focus more on changing parents' behaviors to those that focus more on changing parents' representations of their own attachment experiences.

Attachment and biobehavioral catch-up

The Attachment and Biobehavioral Catch-up (ABC; Dozier *et al.*, 2012) intervention targets three issues known to affect children's attachment security and self-regulatory capabilities. First, parents are helped to behave in nurturing ways when children are distressed because nurturing behavior is associated with secure attachment (Ainsworth *et al.*, 1978). Second, parents are helped to follow children's lead, which has been demonstrated to enhance children's regulatory capabilities (Raver, 1996). Third, parents are helped to behave in ways that are

not frightening because frightening behavior is associated with disorganized attachment (e.g., Schuengel *et al.*, 1999). These issues are targeted through 10 sessions implemented in families' homes with parents and children present. Although the content is manualized, parent coaches are expected to make frequent "in the moment" comments regarding targeted behaviors. For example, when a parent is observed nurturing her distressed child, comments would focus on: specifically identifying the observed behavior, (e.g., "he fell, and you said, right away, 'sweetie, are you ok?'); linking the behavior to the intervention target (e.g., "that's such a good example of nurturing him when he needs you"); and linking to child outcomes (e.g., "that's the kind of thing that will help him to know that he can come to you, no matter what").

The ABC intervention has been shown to be effective in randomized clinical trials in enhancing child attachment security (Bernard *et al.*, 2012). Relative to children randomly assigned to a control intervention, children at high risk for neglect randomly assigned to the ABC showed secure attachments at a higher rate (33% vs 52%, respectively), and disorganized attachment at a lower rate (57% vs 32% respectively). Positive outcomes for the children from the ABC intervention group have also been seen in the areas of diurnal cortisol production (Bernard *et al.*, 2012), emotion regulation (Lind *et al.*, 2014), and executive functioning (Lewis-Morrarty *et al.*, 2012). Further, mothers who received the intervention showed different brain activity (i.e., event-related potentials) when viewing pictures of crying, laughing, and neutral infant faces (Bernard *et al.*, 2013). These effects were observed as long as 3 years after the intervention, suggesting that the intervention helps parents change in fundamental, long-term ways.

Circle of Security

Circle of Security (Hoffman *et al.*, 2006) is a group intervention designed to help parents identify the issues that interfere with parenting the most. Attachment issues are considered to represent a "circle of security," with parents providing a safe haven when children are distressed, and a secure base when children feel prepared to explore the world. Parents are asked to think about whether their own issues (their "shark music," Hoffman *et al.*, 2006) interfere more when they are welcoming the child back for reassurance or allowing the child to move away to explore. Two versions of Circle of Security exist, including a more intensive 20-session format, that is dependent on expertise to assess attachment, and a brief 8-session CD-based version that is not tailored as individually as the longer version. The longer version has been tested in a pre-post-intervention blinded design, and was shown to enhance attachment security (Hoffman *et al.*, 2006). At this point, randomized clinical trials have not been completed but are under way.

Child-parent psychotherapy

Child-parent Psychotherapy focuses on traumatized parents' challenges in behaving in sensitive, nurturing ways with their

young children. The intervention grew from Selma Fraiberg's (1980) psychoanalytic approach that considered the parent's "ghosts from the nursery," or challenges from the past. Alicia Lieberman adapted this intervention to be broader and manualized (Lieberman *et al.*, 2006). Child–parent Psychotherapy is designed to help parents understand how their previous experiences affect parenting in a very real way. The relatively intensive, long-term intervention is intended to provide a safe, playful context. Through randomized clinical trials, Child–parent Psychotherapy has been shown to reduce disorganized attachment (Cicchetti *et al.*, 2006) and reduce children's negative self-representations (Toth *et al.*, 2002).

Preschoolers

Several interventions for older children incorporate attachment concepts with social learning principles to greater or lesser extents. Included among these are Video-feedback Intervention to promote Positive Parenting and Sensitive Discipline (VIPP-SD; Juffer *et al.*, 2008), Incredible Years (Webster-Stratton *et al.*, 2001), Parent–child Interaction Therapy (Eyberg *et al.*, 2001), and others. The most explicitly attachment-based of these interventions is the VIPP-SD, which has been shown in a randomized clinical trial to increase mothers' use of more sensitive discipline strategies (van Zeijl *et al.*, 2006).

Children and adolescents

Fewer interventions are explicitly attachment-based for older children and adolescents than for younger children, although many interventions nonetheless are relevant to attachment issues. Attachment-Based Family Therapy (Diamond *et al.*, 2002) is one of the few interventions that very directly targets attachment issues for this older age group. The treatment focuses on both family and individual processes that can help build trust between the adolescent and parents, and directs attention toward enhancing a relationship in which the parent can effectively protect the child.

Future directions

Clinical implications

Bowlby had strong clinical interests and approached attachment theory from this perspective. Ainsworth, however, was primarily a developmental psychologist. Her role as developmental methodologist focused the field on developmental research for the first several decades of attachment research. More recently, in the last several decades, attachment has been increasingly studied in clinical settings, and attachment-based interventions have been developed. Still, the field of attachment-based interventions is fledgling at this point. This is likely to be a rich area for future development.

Cross-cutting research

Attachment research has been characterized by cross-cutting theoretical and methodological approaches since its earliest

days. Bowlby borrowed from multiple disciplines in articulating his vision of attachment research, most especially considering ethology and evolutionary theory. Thus, connections across human, non-human primate, and rodent research have been made since Bowlby's first conceptualization of the theory. Linkages to physiology have been made by Sroufe in 1977, and by others since. Nonetheless, recent developments in neurobiology and epigenetics and in translational research more generally, make this an especially important focus of research.

Studying extreme conditions

Links between extreme conditions (e.g., orphanage care and maltreatment among humans, separation among non-human primates) and attachment-related outcomes were of interest to Bowlby in his formulation of attachment theory. Such conditions will continue to be important to study in informing what is critical about parenting. These areas represent the historical context and the future for attachment theory and research.

Conclusions

Attachment has emerged as a powerful construct. As Rutter pointed out (2006), much of what Bowlby proposed in the 1950s and 1960s is now accepted within psychology, social work, and even psychiatry. At the time the theory was introduced, though, it was revolutionary. A rich and growing body of empirical work has followed the seminal observational studies of Bowlby and Ainsworth, including significant longitudinal efforts and critical attention to atypical caregiving circumstances. Remarkably, these studies continue to offer strong support for key tenets of attachment theory.

CHAPTER 7

Infant/early years mental health

Tuula Tamminen and Kaija Puura

Department of Child Psychiatry, University of Tampere and Tampere University Hospital, Tampere, Finland

Introduction

The concepts of infancy and infant mental health

Infancy can refer to different age groups. In this chapter we focus mainly on the first year but also cover up to the fourth birthday. During infancy, mental health is very strongly connected to the quality of caregiving relationships, especially to the mutual adaptation capacity of an infant and his/her parents (Mäntymaa, 2006, see Chapters 6 and 8). Infant mental health also requires capacities and opportunities for rapid developmental processes (see Chapter 9).

Pregnancy and family perspectives

Pregnancy is a period when both parents undergo the transition to parenthood. Parental perceptions of the future infant and of themselves as parents are based on their own experiences of being parented and their ideals and fears (Raphael-Leff, 2010). Normally, parental expectations of the infant and parenting include both positive and negative aspects, and parents are able to flexibly resolve these. The birth of the first child transforms the couple into a family, with not only dyadic (parent–parent, parent–infant) but also triadic interactions (mother–father–infant). With subsequent births, the number of dyadic relationships in a family increases, and siblings also shape each other's development (Rao & Beidel, 2009).

The development of the central nervous system of the fetus during pregnancy is affected by the health and actions of the mother, and also by the actions of the other parent. In antenatal clinics, attention should be paid to parental well-being, and to supporting abstinence from substance abuse and smoking. Prenatal mental health problems of both parents, most commonly anxiety and depression, should be appropriately treated without delay, as they are linked to postnatal mental health problems and problems in the parent–infant relationship (Luoma *et al.*, 2001; Davis *et al.*, 2004; Kane & Garber, 2004; see Chapter 28).

Aspects of infant's social and emotional development

Mental development has been understood as a continuous process with developmental steps or leaps, when physiological, motor, cognitive, social, and emotional maturation through integration reach a higher reorganizational level. Psychodynamic oriented, often prominently theoretical research, which has concentrated more on the child's subjective experiences, describes these developmental transition points as bio-behavioral shifts.

Empirical neuropsychological research in turn shows mental development as a continual unfolding of the mind (Bale *et al.*, 2010). Research on vision raised the idea of a critical or sensitive period when the maturation of the visual cortex was shown to be dependent on visual stimuli during a certain time frame. Whether or not this is a more general rule of brain maturation is still unclear, but the remarkable plasticity of brain development has become quite evident (see Chapter 9).

Empirical research starting from Darwin (1872, 1965) notes the emergence of human emotions, and the display and range of emotions go from a few to the highly differentiated many, as well as from action patterns to feelings during the first three years (Lewis, 2008). Before the first developmental milestone or bio-behavioral shift, which occurs at 2–3 months, infants show general distress marked by crying and irritability, and pleasure marked by satiation, attention, and responsiveness to the environment. By 3 months an infant becomes more focused and communicative, including social smiling and the emergence of joy. Also, sadness emerges, especially around the withdrawal of positive stimulus events.

Between 7 and 9 months, infants start to understand that human beings have their own individual thoughts and feelings (theory of mind) and that these can be shared in interaction. By this age, infants' emotional behavior reflects the emergence of six early emotions, called primary or basic emotions (joy, sadness, anger, fear, surprise, and disgust) (Izard, 1978).

Toward the end of the first and during the second year of life, new cognitive capacities emerge, for example, a qualitative advance in understanding symbols, which has been considered to be the basis for learning to speak. Infants/toddlers now recognize themselves in mirrors and photographs. Simultaneously, “self-conscious emotions,” such as embarrassment, envy, and true empathy emerge (Lewis, 2008). Between two and three years of age, cognitive maturation again induces toddlers to learn logical thinking, which greatly increases the communicative options and socioemotional development. The “self-conscious evaluative emotions” emerge, which include pride, shame, and guilt (Lewis, 2008).

After birth, infants’ ability to regulate their own physical needs and emotional states is limited and a caregiving adult is responsible for what is called mutual regulation (Tronick *et al.*, 1986) or attunement (Stern, 1985; Field, 1994). When a caregiver is emotionally available and sensitive enough, infants learn step by step to control their own emotions and behavior, which facilitates further social development (Figure 7.1). Infants also learn to control their behavior through mirroring and social referencing, by looking to the caregivers for emotional guidance (Campos & Stenberg, 1981).

Infants from birth act and behave in individual ways. These differences are considered to reflect inborn temperament features. Primary caregiving relationships, especially infants’ most important attachment relationships, shape and refine infants’ temperamental features, and conversely, an infant’s temperament has effects on the quality of parent–infant interaction and their attachment relationships (see Chapter 8).

Play and learning/teaching are important elements of infant–caregiver interaction and influence not only the infant’s cognitive but also the emotional and social development. Scaffolding, an adult’s ability to provide assistance, and previewing, an adult’s ability to be one step ahead of the infant’s present abilities, are means of offering increasingly complex new information and thus promote development. Development takes place through ordinary interaction during caretaking (Emde, 1991).

Figure 7.1 Transactional relations between self-regulation and other-regulation (Sameroff, 2010).

Cultural influences in infant mental health

Children are shaped by culturally regulated customs, child-rearing practices, and belief systems (Harkness & Super, 1995). The first wave of research on culture and parenting focused on minorities versus dominant culture (Super & Harkness, 1997). Cultural discrimination is still a huge problem with multiple socioeconomic and psychological challenges, in particular for parents with young children (Boris, 2006; von Klitzing, 2006). Studies on migration have shown that recurring or prolonged separations, social isolation, and intensive “homesickness” also affect early parenting. Parenthood is inextricably linked to the culture of origin, but the socialization goals of the parents for their child force them to adapt to a new culture. Thus, parenting may become stressful and conflictual (Meléndez, 2005).

The second phase of research concentrated on cross-cultural comparisons. Several studies have identified interesting differences. For instance, Keller and coworkers (2004) revealed that a community with a proximal parenting style during infancy fostered the toddler’s interdependency and relatedness, and a community with a distal parenting tradition strengthened independence and autonomy.

The third line of research seeks universal features in parenting practices across different cultures. Referring to these empirical studies, Quinn (2003) stated that different cultures use similar, specific ways in their child-rearing practices, even if these practices may vary according to the parents’ cultural values. Three features in parenting practices are common to many cultures: repeating and maintaining the consistency of a child’s experience, creating emotional arousal in a child, and giving moral evaluations of a child.

Currently, both parents and professionals need more evidence-based understanding of culture-specific parenting and its impact on early development. Future research might offer a better understanding of ways to integrate the best practices of child rearing around the world (Tamminen, 2006a, b).

Risk and protective factors

Risk factors

Distal risk factors in infancy can be defined as conditions and events rendering caregivers unable to protect the infant from harm, or to care for his/her basic physiological and psychological needs. Such risks may be long-lasting, like poverty, or appear suddenly like natural disasters, accidents, and armed conflicts (see Chapter 26).

All the major risk factors mentioned may disrupt infants’ development. An important determinant of the effects of traumatic exposure is the caregivers’ ability to restore the sense of safety by successful regulation of infant emotion, sleep, arousal, and attention (Scheeringa & Zeanah, 2001). There is evidence of risk effects being cumulative and further complicated by limited access to health care and education (Walker *et al.*, 2007).

Even outside the most adverse conditions such as institutional rearing (see Chapters 21 and 58) there is now cumulating evidence on how the quality of parenting is a proximal risk factor that may impact mental health in infancy (see Chapter 37). Parental mental and physical health also require consideration as these have an important impact on parenting and the quality of parent care (see Chapter 28). Depression and anxiety are especially common.

Parenthood during adolescence may pose difficult challenges in a phase when adolescents themselves still need psychological, social, and economic support. Adolescent parenting has been associated with poorer adaptation to parental role, poorer social support, increased risk for depression (Reid & Meadows-Oliver, 2007), and adolescent mothers have been shown to be more likely to be insensitive and use more punishment with their infants (Coll *et al.*, 1986). It is likely that the effect of adolescent parenting on child outcome is moderated by coexisting risk and protective factors.

Even in families where there are no apparent risk factors, problems in caregiving may arise if there is a very poor goodness-of-fit between parent and infant (Stern, 1995). A parent who has difficulties in understanding and accepting the behavior and characteristics of the infant may act insensitively in interaction, and also have difficulties in becoming attached to the infant.

Infants' normal psychological development may also be jeopardized by factors directly affecting infant behavior and increasing the perceived burden of parenting. Crying is the infant's main way of communicating distress. In a study of 3259 infants aged 1–6 months, Reijneveld *et al.* (2004) found that 5.6% of parents reported having smothered, slapped or shaken their infant due to crying. Premature infants are often felt to be more difficult to care for, less sociable and parents' attachment to them may vary from normal to avoidant, overprotective or intrusive (Feldman & Eidelman, 2006). Recurrently or chronically sick infants may be at risk for the same reasons, while stressful conditions like poor parenting may increase susceptibility to illness (Mäntymä *et al.*, 2003). The infant may also be difficult to soothe, show irregularity in biological functions and have difficulties in adapting to new situations, that is, have a difficult temperament, or as a toddler have difficulties with impulse-control (Kochanska *et al.*, 2000), making caregiving more challenging (see Chapter 8).

Protective factors and infant resilience

For infants and young children having a relationship with a responsive, warm, and available caregiver is likely the most important factor for positive outcomes (Rutter, 2013, see Chapters 6 and 27). Children with the capacity to elicit support and positive responses from others by their own positive behavior, for example, smiles, may be at an advantage in this regard (Werner & Smith, 2001, see Chapter 8). Distal protective factors include parents' social network, social security services, and organized health care (Petersen *et al.*, 2010).

Special features in assessing infants

Guidelines for assessment

When assessing infants, clinicians face age-specific challenges. Infants and toddlers are active partners when interacting with others, but limited in their communicative skills compared to older children. Clinicians therefore rely greatly on information from caregivers, and on direct observation of infants. As context and relationships are influential, the variation in infant behavior across settings is highly informative (Clark *et al.*, 2004, see Chapter 32). Rapid development during the first three years requires a developmental perspective to differentiate normality from risk and pathology.

A clinical interview is a cornerstone of assessment. Usually it is easiest to start by discussing the problems and symptoms of the infant with the parents and other caregivers. Parental reports and views on the infant's constitutional characteristics and temperament and on the caregiver–infant relationship and interaction are also important.

Severely disadvantaged life conditions may cause developmental deviance while infant developmental delay may cause problems in early interaction, hence the importance of developmental history starting from the prenatal period. Family functioning and cultural and community patterns are important in assessing the quality of care and parenting, and how this may have affected the infant. Parents' characteristics and health are important, likewise the quality of their partner and co-parenting relationships as these affect caregiving.

Direct observation of an infant and his/her interactions with others is another cornerstone in assessment. Observation may quickly reveal problematic areas in parental caregiving. Also, the infant's constitutional characteristics and maturation phase, and affective, language, cognitive, motor and sensory patterns need to be assessed by observation, in addition to parental report, to ascertain how challenging his/her caregiving is, and what skills he/she particularly needs to develop or improve.

Assessment of the infant's mental state

Clinicians can also use parental reports on infant development, behavior and characteristics, and psychological testing for assessing the cognitive, social, and emotional state of an infant. Examples are shown in Table 7.1.

Infant and toddler observation methods

Infant observation is an important method for acquiring first-hand information on the development and well-being of the infant and for screening for signs of pathology. Several structured assessment methods based on infant observation are now in use, of which three examples are described here. The Brazelton Neonatal Behavior Assessment Scale (BNBAS, Brazelton, 1973) is meant to examine the integrity of the neonate's central nervous system and to help caregivers to understand and interact with the newborn. The Baby Alarm Distress Scale

Table 7.1 Examples of parental reports used in assessing infants.

Method	Authors	Age range in months	Purpose	Description
<i>Developmental functioning</i>				
Ages and Stages Questionnaire (ASQ)	Bricker <i>et al.</i> (1999)	1 to 48 months	Screen for delays in communication and motor and social development	Parental questionnaire
Vineland Adaptive Behavior Scales II	Sparrow <i>et al.</i> (2005)	0 to adulthood	Screen for delays in communication, daily skills, socialization, motor skills, maladaptive behaviors	Parental questionnaire
Infant Behavior Questionnaire (IBQ)	Rothbart (1981)	3 to 12 months	Assesses infant temperament and characteristics	Parental questionnaire used mainly for research purposes
Infant Characteristics Questionnaire (ICQ)	Bates <i>et al.</i> (1979)	6, 13, and 24 months	Assesses the construct of temperament, subscales for fussiness/difficulties, adaptability, sociability and persistence, high scores indicating more problems with the infant	Parental questionnaire
<i>Infant behavior and symptoms</i>				
Infant-Toddler Social and Emotional Assessment (ITSEA)	Carter & Briggs-Cowan (2006)	12 to 36 months	Comprehensive checklist for evaluating socioemotional and behavioral problems in infants and toddlers	Parental questionnaire
Brief Infant-Toddler Social and Emotional Assessment (BITSEA)	Briggs-Cowan & Carter (2006)	12 to 36 months	Brief parent report for evaluating socioemotional and behavioral problems in infants and toddlers	Parental questionnaire
Child Behavior Checklist (CBCL)	Achenbach & Rescorla (2000)	18 to 60 months	Comprehensive checklist for evaluating socioemotional and behavioral problems in infants and toddlers	Parental questionnaire, parallel version for other caregivers like kindergarten teachers
Behavioral Screening Questionnaire	Richman <i>et al.</i> (1975)	From 36 months	Designed to document the occurrence of early behavioral disturbances	Parental questionnaire
Checklist for Autism in Toddlers (CHAT)	Baron-Cohen <i>et al.</i> (1992)	18 months	Checklist for detecting autistic symptoms	Checklist administered by health care professional to the parent
<i>Parent interviews</i>				
Mannheim Parent Interview	Esser <i>et al.</i> (1989)	3 months–5 years	Research use	Structured interview covering common problems and symptoms in infancy and toddlerhood
European Early Promotion Project (EEPP) Interview	Puura <i>et al.</i> (2005a)	From birth to 2 years	Research use	Semi-structured interview based on Isle of Wight family assessment interview, covers demographic information, risk factors, behavioral characteristics, and common problems in infancy
Working Model of the Child-Interview	Zeanah <i>et al.</i> (1994)	From birth on	Research and clinical use	Semi-structured interview, assesses caregivers' internal representations of their relationship with the child
Preschool Age Psychiatric Assessment (PAPA)	Egger & Angold (2004)	From 2 to 5 years	Diagnostic interview, research and clinical use	Semi-structured, includes all DSM-IV criteria relevant for children in this age range, all the items in the Diagnostic Classification Zero to Three and additional behaviors and symptoms that may be encountered by toddlers and their families. In addition, assesses the amount of impairment associated with symptoms, family relationships, and environment and life events
Diagnostic Infant and Preschool Assessment Manual (DIPA)	Scheeringa (2004)	From birth to 6 years	Diagnostic interview, research and clinical use	Partly structured and semi-structured interview, includes all DSM-IV criteria relevant for children in this age range

(ADBB, Guedeney & Fermanian 2001) is an observation method for assessing signs of pathology, and was designed to screen for signs of infant social withdrawal reaction as a part of a medical examination in primary care services. The ADBB consists of eight items concerning the behavior and characteristics of the baby (facial expression, eye contact, vocalization, overall level of activity, self-stimulating behavior, briskness of response to stimulation, attraction toward the infant, and relationship between the infant and the observer). The rating is done immediately after observation in a live situation, or on videotape. Higher scores have been found to be associated with insensitive parent–infant interaction and parental mental health problems (e.g., De Rosa *et al.*, 2010; Puura *et al.*, 2013).

An observation scale developed for assessing a particular type of child behavior is the Disruptive Behavior Observation Scale (DB-DOS) for three- to five-year-old children (Wakschlag *et al.*, 2008). The DB-DOS is a 50-min structured observation that is divided into one part with the parent and two parts with the examiner.

Assessment of the parent–infant relationship

Parental reports and observation methods are shown in Table 7.2. Parental reports like the Parenting Stress Index (Abidin, 1997) yield valuable information on how the parent perceives his/her infant, and experiences interaction with the infant.

Table 7.2 Examples of methods for assessing parent–infant interaction and relationship.

Method	Author	Age range	Purpose	Description
Parenting Stress Index (PSI)	Abidin (1997)	0 to adulthood	Assessment of parent–child relationship and parental stress	Parent questionnaire, statements concerning infant characteristics, how the parent feels about the child, and how much stress is caused by child
Infant-Toddler HOME-Inventory	Bradley & Caldwell (1979)	0 to 36 months	Assessment of children's developmental surroundings and parent–child relationship	Semi-structured observation method with an interview, the examiner during a home visit makes observations on the environment of the infant and of parental behavior
Child–Adult Relational Experimental Index (CARE Index)	Crittenden (1981)	0 to 36 months	Assessment of parent–infant interaction in high-risk groups	Observation method, 5 min sequence of videotaped interaction coded for adult sensitivity and child cooperation with the adult
Parent–Child Early Relationship Assessment (PC-ERA)	Clark (1985)	0 months to 7 years	Assessing parent–infant interaction	Observation method, semi- structured procedure with feeding, structured task, free play and separation–reunion sequence videotaped, each 5-min segment of the videotaped scored separately
Global Rating Scales for Mother–Infant Interaction (GRS)	Murray <i>et al.</i> (1996)	0 to 4 months	Assessment of parent–infant interaction in clinical groups such as depression and schizophrenia, social adversity and low-risk/- high-risk groups	Observation method, mother and infant videotaped for 5 min in interaction, rated for maternal mood and behavior, infant social behavior and quality of interaction
Emotional Availability Scales; EAS	Biringen <i>et al.</i> (1993, 1998); Biringen (2008)	0 to 48 months	Assessing global quality of parent–infant interaction	Observation method, parental sensitivity, structuring, nonintrusiveness and nonhostility are scored, and child responsiveness and child involvement, rated from 20 to 30 min long videotape with both structured tasks and free play, also global rating of the dyadic relationship
PICCOLO	Roggman <i>et al.</i> (2013)	0 to 36 months	Assessment and intervention method	Observation method for parental interaction behavior in domains of Affection, Responsiveness, Encouragement and Teaching, coding made in live situation or from 5-min videotaped interaction sequence

Assessment of triadic interaction and coparenting

Lausanne Triadic Play (LTP, Fivaz-Depeursinge and Corboz-Warnery, 1999) was developed to assess how both parents and infant interact and coregulate the interaction in a task where they alternate between dyadic and triadic interaction (Figure 7.2). The parents' ability to negotiate changes and show mutual respect in the interaction indicates how well they can function jointly as parents. Smooth and unproblematic coparenting has been shown to be associated with better child outcome (McHale & Rasmussen, 1998; Schoppe-Sullivan *et al.*, 2009).

Integrating the information from the assessment

The diagnosis and intervention plan is based on appropriate assessment, and entails identifying both strengths and weaknesses of the infant and his/her parents, in the whole family, and in society. Parental reports with data from other caregivers and clinical objective data on the infant's development and behavior

are used to form a comprehensive understanding of the infant and his/her problems. In observed behavior, mutual positive affect, shared pleasure, and mutual engagement between parent and infant are usually seen in nonproblematic interaction, whereas parental flat or negative affect in the interaction, infant withdrawal or avoidant behavior, and slight mutual engagement and pleasure between parent and infant usually indicate problems.

Parental reports and clinical data may yield similar results, for example, when parents have noticed a delay in the development of the infants' skills that is also apparent in observation or in psychological testing. More often than not, there are minor or major discrepancies between parental information and other caregiver reports and clinical observations. A common example is a depressed or exhausted parent who may find the normal needs of an infant or toddler extremely demanding, and report the infant to be difficult or have behavioral problems. The child may also have behavioral problems with one parent but

Figure 7.2 Lausanne Trilogue play situation.

not with the other, indicating a problem more likely in that particular relationship or context than in the infant. The parents may also fail to see or report problems in their relationship or in the behavior of the infant, even though these are observable in the assessment. The latter indicates problems in the ability or willingness of the parent to note and respond to the infant's needs.

Common problems versus pathways to psychopathology

What is a problem, a symptom, or a disorder?

Newborn babies are unique individuals who differ greatly. Parents and their life situations also vary. The transition to parenthood and the maturation of biological and psychological regulation mechanisms in caregiving interactions take time; no wonder problems in everyday caretaking and in infant behavior are common, with up to 30% of parents reporting problems (Reijneveld *et al.*, 2001; Crnec *et al.*, 2010).

If the problems are more severe and the buffering capacity of a caregiving relationship is exceeded more permanently, an infant may show more specific symptoms as a sign of general distress, such as withdrawal, irritability, or regulatory difficulties. If these specific symptoms occur in more than one relationship and in different settings, and if there are several symptoms, these should be considered as signs of maladaptive processes or early steps to possible psychopathological trajectories.

In cases of various, serious, and constant symptoms during infancy, the mental health of a young child needs to be properly assessed. Although the empirical evidence of psychiatric disorders in infancy is still quite limited and mostly based on small-sized clinical samples, the possible existence of a mental disorder should be evaluated. If the criteria for a psychiatric disorder (according to ICD-10/11, DSM-5, or The Diagnostic Classification System for Mental Health and Developmental Disorders of Infancy and Early Childhood, DC: 0–3R, 2005) are fulfilled, even an infant is considered to suffer from a disorder. Although the ICD- and DSM-systems take different approaches to diagnostic classification, the main criteria for various disorders are basically quite similar, and the DC: 0–3R-system offers descriptions on how infants and toddlers may exhibit various symptoms. However, it should be noted that the main research gaps in infancy are to be found in the validity of the classification of early disorders and the reliability of diagnostic assessments. Therefore, epidemiological studies on many psychiatric disorders during infancy are still virtually nonexistent.

In the diagnostic assessment of an infant's mental health, both over- and underestimations should be avoided. One should not label problems in young children and in early relationships as medical conditions without strong evidence of diagnostic criteria being met. In addition, the diagnostic processes of infant psychiatric disorders raise specific questions, most notably the

need for diagnosis of relationship disorders (Smith Slep & Tamminen, 2013).

Nevertheless, slowly accumulating research findings indicate that mental disorders exist in all ages during the life course. For very early years, this has been shown in an epidemiologically and clinically well-designed birth cohort study in Denmark (Skovgaard *et al.*, 2007). Also, Möricke with his colleagues conducted an analysis of 6330 parents' reports of their 14–15 month old infants' behavior and symptoms in a population-based study. They concluded that even in infancy certain distinct and disorder relevant developmental profiles can be recognized (Möricke *et al.*, 2013).

Young children with psychiatric disorders should receive therapeutic help as early as possible. Many early interventions have demonstrated their effectiveness in treating young children and their parents in separate single studies, but replications of these results and meta-analyses of several studies are sparse. Qualified infant psychiatric services are still globally quite rare but interventions may also be provided by other services and by other professionals working with infants and toddlers.

Problems with sleeping, feeding, and eating

A newborn infant sleeps approximately 16–17 hours per day; by six months of age, sleep often decreases to 13–14 hours with one longer period; and around one year of age, the infant's circadian timing system has developed so that the sleeping–waking cycle has diurnal organization. However, individual variations are wide. Sleep patterns are regulated by both biological and physiological factors (e.g., brain maturation and neurotransmitters involved in the promotion, maintenance, and timing of sleep) and psychological processes (e.g., behavioral and relational aspects and cultural norms).

Parental concerns about infant sleep problems are common during the first three years. Significant sleep difficulties among this age group occur in 15–35%, and most often entail difficulties initiating sleep and waking at night (Crnec *et al.*, 2010).

Various kinds of parent education and behavioral interventions and therapies have been evaluated in controlled experimental studies with quite large treatment effect sizes (Sadeh, 2005; Crnec *et al.*, 2010; see Chapter 70).

Different severity levels of feeding and eating problems occur in approximately 20–40% among normally developing 0- to 3-year-old children and in up to 80% among children with developmental disabilities (Bryant-Waugh *et al.*, 2010). Around 1–3% of infants suffer from severe feeding difficulties associated with poor weight gain (Skovgaard *et al.*, 2007; Chatoor & Macaoay, 2008).

An infant may have difficulties in reaching and maintaining a calm state during feeding and a caregiver may be unable to help the infant. A lack of caregiver–infant reciprocity may also create feeding problems. Young children also have sensory food aversions, so that a child consistently refuses to eat foods with specific tastes, textures, or smells but eats preferred foods without difficulty. Maternal worries about child

underweight partially explain the development of negative feeding interactions (Gueron-Sela *et al.*, 2011).

Somatic illnesses and medical conditions may create feeding and eating problems and these may persist even after the medical situation improves. Some young children exhibit food refusals after insertion of nasogastric or endotracheal tubes or suctioning. Other clear insults to the gastrointestinal tract may also trigger intense distress in the infant and lead to severe feeding problems (Arts-Rodas & Benoit, 1998; Chatoor & Macaoay, 2008).

There are also feeding problems with apparently none of these etiological backgrounds, and when the condition is severe enough it has been called infantile anorexia. These feeding problems are serious enough to impede adequate weight gain or produce weight loss and have been suggested to be a psychiatric disorder if they continue at least a month without improvement. Regurgitation or reflux may sometimes be part of the disorder. Persistent eating of nonnutritive substances, so-called pica, is most common in children with intellectual development disorders, but may also occur in maltreated or neglected young children.

Regardless of the etiology, feeding difficulties often affect the infant–caregiver relationship and to successfully treat the problem or disorder, the relational aspects should be considered (see Chapter 71).

Problems in emotion regulation and early mood disorders

Infants have some behaviors to regulate their emotional states (e.g., looking away, self-stimulation, and self-comforting). However, infants' regulation capacities are immature and poorly coordinated, and emotion regulation is dependent on the actions of the caregivers. Throughout their development, children learn and internalize repeated dyadic patterns of emotion regulation.

Both infants and their caretakers share emotional states when interacting. One of the major features of early interaction is how infants and parents constantly attune their gestures, vocalizations, movements, and actions to each other's behavior. This is considered an important part of emotion sharing and regulation. Well-attuned interaction is pleasurable and mis-attunement creates concerns in both partners.

Both infants and their caretakers may have many kinds of problems in emotion regulation and sharing. An infant's difficult temperament or a parent's depressed mood may create difficulties. Also, environmental stressors may affect family atmosphere and disrupt sensitive parent–child interactions. Negative emotions, dissatisfaction, and disappointment are consequently quite normal in new parents; so also are fussing and crying in infants.

Parental psychopathology complicates the dyadic emotion regulation more seriously, and poor quality of attachment relationships or severe traumas may also impair joint emotion regulation and maturation of the child's own affect control. These risk factors may also be cumulative in increasing the

likelihood of a mood disorder in a young child (Guedeney *et al.*, 2013).

If a child has several symptoms occurring most of the day, more days than not, and if these symptoms are generalized across different settings and relationships, and if there is a clear change from the child's earlier mood and behavior, even a young child is considered to have a depression or anxiety disorder. Disorder also entails diminished functional capacities, for example, difficulty focusing attention or concentrating or responding to caregivers, restlessness or loss of energy, and loss of already acquired skills, all of which may impede a child's development.

A very young child can present with depressed or irritable mood or anhedonia, and markedly diminished pleasure or interest in activities such as play or interaction with caregivers. There may be significant weight loss or gain, insomnia or hypersomnia, and psychomotor agitation or retardation. The recurrent and chronic nature of childhood depression underscores the need for early attention to this public health problem (Field *et al.*, 2006; Mathers & Loncar, 2006). Anxiety disorders, notably separation anxiety, can also present in this age group (see Chapter 60).

Problems with behavior regulation and aggression

Children's ability to coordinate and control their own actions and behaviors matures rapidly during the first years of life, and development continues throughout childhood and adolescence. Since emotion regulation is also immature in early childhood, negative behaviors and temper tantrums are frequent. The period after infancy has aptly been called the "terrible twos." Studies on the normative development of externalizing behaviors indicate an increase until the second and third year of life, with a decrease after this age (Tremblay *et al.*, 2004), although considerable individual variations exist.

There are contradictory views on whether it is appropriate to use the term disorder for young children with significant levels of aggressive and disruptive behavior, because intentionality of hostile actions, reduced empathy, guilt, and concern toward others, which are descriptions of core symptoms in these disorders, may not be similar at young ages (Gill & Calkins, 2003). However, in the United States it has been estimated that 1 in 11 preschoolers meets formal DSM criteria for a disruptive behavior disorder, 1 in 14 for an oppositional defiant disorder, and 1 in 30 for a conduct disorder (Egger & Angold, 2006). Early disruptive behavior problems occur in different cultures, exhibit considerable stability, are associated with profound academic and social disability, and increase the risk for later psychopathology and criminality (Copeland *et al.*, 2007; Burke *et al.*, 2010).

Psychosocial treatments focusing on parent–child interaction have demonstrated a large and sustained effect (Comer *et al.*, 2013, see Chapters 37 and 40).

Problems related to adverse experiences and effects of severe trauma

Facing ordinary difficulties and solving everyday problems are considered important promoters of early mental development.

Experiences of surviving adversities and overcoming exceptional challenges may also play a role in the development of resilience.

Severe trauma such as life-threatening injury to the child or family members or chronic child battering or sexual abuse are overwhelming experiences and may lead to posttraumatic stress disorder even in infants and toddlers (Scheeringa & Gaensbauer, 2000).

In posttraumatic stress disorder, the child shows evidence of re-experiencing the traumatic event(s) (e.g., compulsively driven, anxiety-provoking play, recurring nightmares of the traumatic event, flashbacks, and dissociation). The young child also has numbing of responsiveness (e.g., withdrawal and avoidance) and clear developmental problems. After a traumatic event, the child exhibits symptoms of increased arousal. As in all other mental disorders, a young child's functional capacity is also clearly impaired.

Physical and psychological abuse or chronic neglect and deprivation of a very young child by caregivers may also lead to a specific disorder, which in the ICD and DSM systems is described as attachment disorder and in the DC: 0–3R as a deprivation disorder with either an inhibited or indiscriminate pattern (see Chapter 58).

Empirical studies of posttraumatic stress disorder in infants and toddlers have advanced further than that of other disorders in early childhood and findings on the long-lasting consequences of early severe trauma are emerging (Heim *et al.*, 2010). The psychological and biological “footprints” of early trauma are now the focus of intensive research (e.g., negative synaptic circulates, overacting stress reactions, immunological changes) and cumulating evidence indicates traits of pathological development for many somatic and mental disorders (Ladd *et al.*, 2000, see Chapter 23).

Disorders in development and communicating

Variation in the rate of early maturation is wide and slowly developing young children usually grow up normally. The developmental process may also include phases of regression, for example, as a reaction to environmental stress.

However, developmental disorders initiating and manifesting during the first years of life can and should be detected early. Although a developmental disorder is usually obvious, it may at first be difficult to know precisely whether it is intellectual disability, a pervasive developmental disorder, or a reactive attachment disorder. These serious disorders are presented with descriptions also covering infancy and toddlerhood in Chapters 51, 54, and 58.

Special features of interventions in infancy

Goals for treatment

The main treatment goals are improving the developmental environment of the infant so that psychopathology can be

prevented and present and future suffering avoided or alleviated. During pregnancy, infant mental health promotion includes adequate health and mental health care of both parents. On a global scale, the provision of adequate nutrition, housing, physical safety, and hygiene are important together with providing each infant with good and sufficient care and emotional interaction with the parents or caregivers. The most common intervention in infancy is sharing the worries of parents and providing guidance or education, both in naturally existing peer or relative relationships, in primary care services, and in the services of nongovernmental organizations. For families with elevated need for support, that is, when the parents or the infant, or their interaction need to be treated for identified severe problems or symptoms, several intervention models and psychotherapeutic techniques have been developed. There is no research on psychotropic medication with infants and toddlers, and no knowledge of their long-term effects on brain development.

Preventive parent–infant programs

The focus of preventive parent–infant programs in infancy is the enhancement of effective, positive parenting, so as to enable children's development and to manage behavioral and emotional problems where necessary (see Chapters 17 and 37). Preventive programs in infancy may include home visiting by nurses on a regular basis from pregnancy until the child's third birthday, be center-based or include both home visits and center-based services. Reported positive results from preventive programs include increased parental sensitivity and emotional support (Love *et al.*, 2005; Puura *et al.*, 2005b), children's better executive functioning and better behavioral adaptation in toddlerhood (Olds *et al.*, 2004), and better mental health in middle childhood and adolescence (Aronen, 1993; Aronen & Kurkela, 1996). However, in studies reporting effect sizes they have been from small to moderate (Davis *et al.*, 2005; Olds *et al.*, 2007), and in many studies the effects favoring intervention families have been limited to subgroups (Olds *et al.*, 2007). Olds *et al.* (2007) examined 16 preventive programs and concluded that the strongest evidence exists for programs with nurse home visiting in high-risk families, focusing on the improvement of prenatal health, the child's health and development, and parents' own economic self-sufficiency.

Parent–infant therapies

When problems are perceived in the interaction and relationship of the infant with one parent or caregiver, parent–infant therapy may be used as the sole treatment or in more complex cases as a part of multimodal treatment. In parent–infant psychotherapy, the focus of the treatment is the parent–infant relationship, not the infant or the parent as individuals (see Chapter 40). The goal of the psychotherapy is to sensitize the parent to the infant's needs by helping him/her to perceive and understand the infant's cues, and to respond to these appropriately. This in turn helps the infant to regulate his/her emotional and physiological states,

Figure 7.3 WAIMH affiliates 2013. Source: Reproduced with permission of WAIMH.

and promotes his/her skills and capacity for initiating and sustaining interaction with the parent, both for learning purposes and for using the relationship as an emotionally secure base.

The approaches used can be divided into psychodynamically oriented parent–infant psychotherapies concentrating on the parent’s representations, more behaviorally oriented interactional parent–infant therapies like the Interactional Guidance (McDonough, 2005), and parent–infant therapies integrating elements from both approaches. Some approaches emphasize the infant’s active involvement and role as the initiator of interaction, as in Watch, Wait, and Wonder (WWW; Cohen *et al.*, 1999) or Theraplay (Jernberg & Booth, 1998). In the review of Doughty (2007) of three randomized controlled trials, Interaction Guidance resulted in significant improvements in maternal sensitivity and sensitive discipline, and a decrease in the child’s overactive behavior in a sample of infants with externalizing disorders. Robert-Tissot *et al.* (1996) compared Interaction Guidance and psychodynamic therapy for 75 mothers with behaviorally disturbed infants, and found that both interventions reduced infant symptoms, reduced maternal intrusive behavior and negative affect, and increased maternal self-esteem and infant cooperative behavior. Similar results were obtained by Cohen *et al.* (2002), who divided 67 clinically referred mothers and infants aged 10–30 months to groups receiving WWW or psychodynamic mother–infant therapy. However, research on the efficacy of parent–infant therapies is still scarce.

Family and group interventions

For families where the main concerns are problems of parenting or of the marital relationship, systemic family-centered treatment or family therapy may be an effective way to change dysfunctional interaction patterns. Family therapy may also be offered as the treatment of choice for families with infants and toddlers diagnosed with an illness affecting their development or behavior. Family therapy can be particularly useful for families with infants undergoing a transition, for example, the birth of a sibling or bereavement.

In family therapy, the parents’ thoughts and feelings concerning their child and the family situation are elicited to build a therapeutic relationship. Family therapy sessions are then focused on how parents can practice sensitive, coherent coparenting in the presence of the child’s disorder or illness. In their meta-analyses of 70 studies, Bakermans-Kranenburg *et al.* (2003) concluded that the most effective systemic interventions focused on helping mothers develop sensitivity to their infants’ cues, involved fathers as well as mothers, and spanned no more than 15 sessions. However, the number of studies on family therapy in infancy is small.

Group therapeutic interventions have also been developed and used in treating parents and infants. According to Barlow and Parsons (2010), group-based parenting programs may be effective in improving the emotional and behavioral adjustment of children under the age of 3. These interventions have usually

been used with mothers with psychiatric problems (Pedrina, 2004), but recently also with other high-risk samples. Examples of treatment models for multirisk families include the Circle of Security (Powell *et al.*, 2009) used with delinquent mothers (Cassidy *et al.*, 2010) and psychodynamic group therapy for substance abusing mothers (Belt *et al.*, 2012). Although a number of treatment programs have been developed for multirisk families, there is currently no definite evidence of their efficacy.

Multicomponent interventions for high-risk groups

In families overburdened by parental mental health and substance abuse problems, low social support, unemployment and poverty (Zeanah & Smyke, 2008), a multicomponent strategy including networking with social services, community health services, services for substance abusers, and adult psychiatric services is often necessary. The first task is to assess what services are needed to ensure that the needs of the infant or child are adequately met. The aim is to introduce some stability and predictability into the life of the family. Once this is achieved, parents may be able to engage in working on their parenting with the methods described (Luthar & Walsh, 1995). There is currently no definite evidence of the efficacy of multicomponent interventions.

In the most severe cases, infants have been admitted to residential psychiatric treatment, earlier in adult mental hospitals and nowadays in child psychiatric units. The focus of the treatment in adult mental hospitals has been on the mental health of the mother, and having the infant in the hospital seems to help psychotic mothers to recover more rapidly. The development of infant psychiatric practices has moved toward short, intensive periods of treatment focusing on infant mental health as well as parental mental health (Tamminen & Kaukonen, 1999).

Conclusion

The field of infant mental health is still in its infancy. There are wide gaps in our knowledge. There is still a great need for studies on the validity of diagnostic criteria and the reliability of assessment processes concerning infants and toddlers. However, parents and professionals around the world increasingly recognize the need for and meaningfulness of working with infant mental health problems and disorders (Figure 7.3). Also, there is slowly cumulating research evidence on the effects of early therapeutic interventions, although one should be especially cautious when intervening during this particular life phase.

CHAPTER 8

Temperament: individual differences in reactivity and regulation as antecedent to personality

Nathan A. Fox and Olga L. Walker

Department of Human Development and Quantitative Methodology, University of Maryland, College Park, MD, USA

Introduction

Research on infant temperament has a long history in developmental psychology. With an increased interest in the origins of psychopathology and a renewed appreciation for the influence of individual differences on behavior, considerable recent work has characterized early dispositions and their developmental trajectories. The current chapter is a nonexhaustive review of this vast literature. Interested readers are referred to Chen & Schmidt (2015) for a broader overview of the issues raised here. In the current chapter, we first provide a definition of temperament and contrast it with a definition of personality. We then review a number of the conceptual models used to think about individual differences in temperament and follow that with an overview of assessment methods for studying temperamental behaviors. We briefly review work on the link between genes and individual differences in temperament followed by a broader discussion of the temperament of behavioral inhibition. In the final section of this chapter, we examine the links between temperament and psychological adjustment across age, including the emergence of psychopathology. We end with comments about work examining other types of temperament (exuberance) and suggestions for the future.

Definitions and conceptual distinctions between temperament and personality

Temperament is considered the behavioral style that an infant or young child exhibits in response to a variety of stimuli and across contexts. Chess and Thomas (1986) introduced the concept of temperament to psychology and child psychiatry in the United States; they described temperament as the style of behavior (the “how”). This contrasts with views of personality, which include

the content of thought, coping styles, values, and beliefs of an individual (the “what”). Some have argued that temperament is stable across development and could be reflected in personality, though empirical evidence suggests only modest stability (Degnan & Fox, 2007). Personality reflects, as well, patterns of behavior, emotions, and cognition and is focused specifically on aspects of the self (Rothbart, 2011). Though temperament and personality have much in common (see Shiner & Caspi, 2012), they differ in fundamental ways. Temperament is thought to reflect individual differences that are “biological” in origin (whether that be genetic, environmental, or both). Personality is considered to reflect the accruing influences of family, peers, and contexts across development. Temperament is commonly viewed as reflecting “innate, biological” factors. Temperament emerges early in life, evident even in the newborn period, and manifests in other behaviors during the toddler and preschool period that are viewed as “inborn” or maturational (Rothbart, 2011). Personality, on the other hand, emerges later in life to encompass processes learned into adulthood. Temperamental differences exert an influence on cognitive and social development early in life. They form the foundation for personality or perhaps are at its core. Personality traits, on the other hand, deal with issues of self-esteem and self-concept that necessarily involve the child’s interactions with multiple contexts and individuals. While those interactions may be initially guided by temperamental style, they are soon modified by ideas of self-worth and self-concept in multiple areas (social, academic, physical) that form the basis of personality.

Given that personality traits increasingly influence behavior across development, one issue is whether temperamental dispositions display continued stability over time. If there is a good deal of overlap between temperament and personality and if personality emerges out of temperament, then measuring unique temperamental dispositions in older children and adults

Rutter’s Child and Adolescent Psychiatry, Sixth Edition.

Edited by Anita Thapar and Daniel S. Pine, James F. Leckman, Stephen Scott, Margaret J. Snowling, Eric Taylor.

may be difficult. A related issue is how the same temperamental disposition is expressed at different ages. One way to approach this problem is to assume that the “latent” temperament is manifested in different behaviors over time. For example, at four months of age, infants can be identified with a disposition to react with high intensity motor activity and negative affect to novel or unfamiliar stimuli. Such infants are likely to display behavioral inhibition in the toddler period and social reticence later in childhood (Fox *et al.*, 2005). But the personality trait of neuroticism that may describe the same individual as an adult is the result of complex cognitive processes of self-evaluation. Hence, it may be difficult, if not impossible, to identify constructs that separate at older ages the temperament element in personality.

Approaches to the study of temperament

Alexander Thomas and Stella Chess

One highly influential study in the revival of temperament research was a longitudinal investigation by Thomas, Chess, and colleagues (Thomas *et al.*, 1963). Their New York Longitudinal Study (NYLS) formed the basis of their ideas about temperament, noting patterns of individuality in infant reactivity, including sleep–wake cycle, eating behavior, and response to external stimuli. Their work followed children’s development through early childhood. While not widely known, their collaboration with Herbert Birch provided a critical framework. Birch was a colleague of Schneirla, a psychobiologist who wrote about the role of stimulus intensity and approach withdrawal responses in motivated behavior (Schneirla, 1959). With Birch’s help, Thomas and Chess organized their observations into nine temperament dimensions that were defined in infancy to form three main temperament groups: (1) easy, (2) difficult, and (3) slow to warm up. Their claim was that these temperament groupings remained fairly stable over time (Thomas *et al.*, 1970).

Thomas and Chess focused on parent–child interactions and coined the phrase “goodness of fit” (Thomas & Chess, 1977), which proposes that positive developmental outcomes are more likely to occur when a match exists between an infant’s temperament and environmental characteristics (e.g., parenting). Thus, when nature and nurture harmoniously mesh, adaptive outcomes are most probable. However, when there is conflict or a mismatch between temperament and context (parenting behavior or parent expectations), the child is at heightened risk for behavioral problems. Thomas and Chess were among the first to propose that temperament was critical for understanding child development. They also urged both parents and teachers to recognize these differences and assist children of different temperaments to adapt to various environmental challenges (Thomas *et al.*, 1970).

Mary Rothbart

Temperament has also been conceptualized in motivational terms along an approach-withdrawal-systems framework.

Across species, approach and withdrawal behaviors vary with the intensity of stimuli needed to invoke reactivity, with withdrawal occurring when stimulation is intense and approach occurring when it is more subdued (Schneirla, 1959). Rothbart expanded on these ideas (Rothbart, 1981). First, she adopted a unique conceptual approach to the study of reactivity, as one component of a two-part temperament system. In early infancy, she argued that children primarily differ in their reactivity to sensory stimuli, particularly to novel and intense stimulation. She measured reactivity in the infant by assessing the latency to respond, the intensity of the response, and the duration of that response both behaviorally and physiologically.

While variations in reactivity influence an infant’s capability to maintain homeostasis, infants also vary in a second key temperament component, their ability to self-soothe and regulate reactivity, which emerges over the first years of life, with important individual differences. Thus, the self-regulatory aspect of temperament develops over time. Rothbart identified attention as critical, and collaboration with Michael Posner (Rothbart *et al.* 1990; Posner & Rothbart, 2000) cemented links among temperament, development, and the neural circuitry of attention-based self-regulation. Rothbart (1981) described several temperament features that matured with experience, reflecting a continuous dynamic between reactivity and regulation (Rothbart, 1989). This produced a unique emphasis on regulation, which varies developmentally among children, to modulate the timing and intensity of an individual’s reactivity (Rothbart, 1989), particularly through maturation of attentional strategies (Rueda *et al.*, 2004). Over the first months of life, infants switch from a stimulus-driven, externally reactive attention system to a system with more voluntary executive attentional control (Rothbart *et al.*, 1990, 2004). Children are able to resolve conflict more easily, flexibly shift and adapt their response, and inhibit certain dominant responses, thoughts, and emotions to act more appropriately.

Jerome Kagan

Jerome Kagan has for much of his career studied individual differences in infant and child temperament. His longitudinal studies highlighted issues of stability, individual differences, and factors that influence change, with an emphasis on neuroscience (Kagan & Moss, 1962; Kagan, 1971). Perhaps his greatest influence on the field of temperament has been the work on one particular temperament type, known as “behavioral inhibition” (García Coll *et al.*, 1984; Kagan *et al.*, 2007). Initially, Kagan and colleagues identified toddlers who were wary and vigilant to unfamiliar stimuli and contexts. These individual differences appeared to persist into childhood and adolescence and form the core for what personality theorists would call neuroticism. Subsequent to these findings, Kagan described individual differences in reactivity to novelty early in the first year of life, which he claimed reflected the temperament of the child. Infants who displayed high levels of limb movement and distress to novelty had a high reactive temperament and this temperamental disposition served as the basis for subsequent inhibited and shy

behavior. A salient feature of Kagan's approach was not only the identification of high-reactive (typically 15–20% of the sample) infants but the claim that these infants represented a category or temperament type different from less reactive children. The notion is that the confluence of behavioral and physiological reactivity identified this group as unique and a temperament type different from other temperaments. Much as there are physical and biological differences as a function of genetic mutation (e.g., Down syndrome) that set those individuals apart from others without the mutation, so too there are infants with a particular temperament that are different (not just more extreme on some continuum) from others. Although current approaches in temperament research take a more continuous approach to thinking about individual differences in behavior, Kagan's arguments about temperament types continue to influence the field. Kagan's work has considerably shaped the field of temperament over the past two decades for a number of important reasons. His measurement approach has included both behavioral and physiological assessments to characterize this temperament. The pattern of physiology of the high-reactive temperament type is one of heightened autonomic reactivity, elevated stress hormone response, heightened startle, and freezing or avoidant behavior. This "package" of biology and behavior is similar to the pattern of behavior and physiology found in rodent and nonhuman primate models of threat conditioning. Hence, Kagan's work drew great interest from neuroscientists studying the threat system in animal models. As well, the community of biological psychiatry found Kagan's description of this temperament intriguing as it provided a possible basis for understanding at least one origin of anxiety symptoms in adults. The link that has been drawn by others between the temperament of behavioral inhibition and emerging psychopathology has been an important part of the temperament story over the past 20 years.

Assessment of temperament

The two most common methods of measuring temperament are questionnaires and behavioral observations. Age-appropriate questionnaires quantify temperament from parent, teacher, or self-report, with different measures at different ages (e.g., The Infant Behavior Questionnaire—Revised [IBQ-R]; Rothbart, 1981; Garstein & Rothbart, 2003; Toddler Behavior Assessment Questionnaire [TBAQ]; Goldsmith, 1996; The Early Childhood Behavior Questionnaire [ECBQ]; Putnam *et al.*, 2006; The Children's Behavior Questionnaires [CBQ]; Rothbart *et al.*, 2001; Putnam & Rothbart, 2006; Early Adolescent Temperament Questionnaire—Revised [EATQ-R]; Ellis & Rothbart, 2001; Ellis, 2002). Studies examining the validity and reliability of these measures have consistently found three factors: Extraversion/Surgency, Negative Affectivity, and a dimension measuring self-regulation (Orienting/Regulation in the IBQ-R and Effortful Control in the ECBQ, CBQ, and EATQ-R). The latter factor (self-regulation) is conceptualized as emerging over the preschool years, possibly due to developmental shifts in

self-regulation being mainly externally regulated by caregivers during infancy to being internally regulated during early childhood (Garstein & Rothbart, 2003). These three main factors appear to be similar to some dimensions of adult personality (Ahadi & Rothbart, 1994; Rothbart *et al.*, 2004; Rothbart & Bates, 2006). Interestingly, findings with the EATQ-R reported a fourth dimension: Affiliativeness (Ellis & Rothbart, 2001), which is defined as desiring closeness with others, independent of shyness and surgency (Putnam *et al.*, 2001).

Behavioral observations have also been used to measure infant and toddler temperament. Figure 8.1 depicts the context in which such observations are made in infants, toddlers, and school-aged children. As conveyed by these pictures, the contexts of such observations are quite different at different ages. However, at each age, the context is designed to elicit behaviors thought to reflect core aspects of temperament, be it exposure to a novel mobile in infancy, a toy robot in toddlerhood, and novel peers during school age. Various standardized batteries exist for assessing temperament.

The Laboratory Temperament Assessment Battery (LAB-TAB; Goldsmith & Rothbart, 1991) is one such standardized observational measure. The LAB-TAB parallels parent-report questionnaires of Rothbart and colleagues (i.e., IBQ-R and TBAQ). There are two aspects of this battery that make it unique: first is the idea that reactivity and regulation can be measured in part by children's expression of discrete emotions in response to various elicitors. As such, the battery emphasizes the coding of facial expressions of emotion. Second, the battery elicits both reactivity and regulation, with different elicitors for different age groups. Examples of the elicitors include presenting the infant or toddler a toy behind a plastic barrier (to elicit frustration, anger, and approach), or presentation of scary masks (to elicit fear and avoidance).

The Lab-Tab has a manual and a set of behaviors to be coded in response to the various elicitors. Other temperament batteries are similarly structured, having a set of standard elicitors and a set of behaviors to be coded. One such system, described by Kagan *et al.* (1988) and Fox *et al.* (2001b) has been used to characterize behavioral inhibition. This system centers on the idea that behavioral inhibition reflects a child's disposition to respond with heightened vigilance, withdrawal and negative affect to novel, uncertain, and unfamiliar stimulus events. The child is exposed to a series of events (an unfamiliar adult approaching and asking the child to play, a toy robot) and behavior is coded for latency to approach, vocalization, and affective response, with ratings combined to create composite scores which rate levels of withdrawal and negative reactivity, reflecting the temperament of behavioral inhibition.

Temperament questionnaires have advantages and disadvantages. One advantage is that parents observe their children in many situations (Kagan & Fox, 2006); another is their ease of use. Disadvantages include their potential for introducing biases, based on parents' individual experiences or misinterpretation of questionnaires (see Kagan, 2000; Kagan, 2003; Kagan & Fox, 2006). Cross-informant correlations are typically low

Figure 8.1 Three approaches to identifying young children with behavioral inhibition: (a) reactivity in infancy to novel objects (mobiles); (b) response to unfamiliar objects (a toy robot) in the toddler period; (c) play with unfamiliar same-age peers during preschool age.

to moderate (Rothbart, 1981; Goldsmith 1996; Rothbart *et al.*, 2001; Garstein & Rothbart, 2003). Behavioral assessments are more costly, more labor intensive, which creates other disadvantages (Kagan & Fox, 2006). Moreover, correlations between behavioral observations and parent report of temperament are low to moderate as well (Rothbart *et al.* 2000; Kagan & Fox 2006). Since both measures have advantages and disadvantages, combining the two approaches may more fully capture temperament than relying on either approach alone (Wachs & Bates 2001; Calkins *et al.* 2002; Kagan & Fox 2006; Rothbart & Bates 2006).

Genetic origins of temperament

The idea that temperament is “innate” raises questions about genetics. Research has approached these questions through behavior genetics and, more recently, candidate-gene studies. Behavior genetic approaches comparing monozygotic and dizygotic twins (see Chapter 24) find modest-to-high temperament heritability, particularly for the temperament of fearfulness, (Louisville Twin Study, Matheny, 1989; Colorado Twin Study, Robinson *et al.*, 1992; Smith *et al.*, 2012). A second approach

focuses on molecular genetics, usually adopting the so-called candidate-gene approach, which has been questioned in recent years. This includes studies of the dopamine D4 receptor gene and the serotonin transporter gene. More recently, work with candidate genes has examined the interaction of genes with both positive and negative environments from an approach often called differential susceptibility (Belsky & Pluess, 2009). These particular gene variants (sometimes called plasticity genes) are thought to provide protection and, in fact, result in optimal outcomes in the context of certain supportive or facilitative environments above and beyond what is afforded to noncarriers. Alternatively, in the context of stress or harsh environments, they result in detrimental outcomes. For example, Bakermans-Kranenburg and van IJzendoorn (2006) examined the effects of differences in maternal sensitivity on externalizing behavior amongst children according to carrier status of the 7-repeat allele of a variant in a gene encoding the dopamine D4 receptor. They found that children who carried this allelic variation and whose mothers were insensitive had the highest externalizing behavior, while those with the same gene variant but high in maternal sensitivity had the least externalizing behavior of all. There are now multiple instances of studies like

this one with different candidate genes (serotonin transporter [5-HTT]; mono-amine oxidase [MAO-A]) and different types of environmental contexts and obviously different types of child outcomes. The interpretation of candidate-gene studies is discussed in Chapter 24. There remains inconsistency in the findings and questions about the *a priori* or *a posteriori* choice of which genes and which variants in the gene are selected and which environments and which outcomes are examined in certain studies.

There is however, amongst the differential susceptibility approach, a notion compatible with temperament in which individuals are thought to vary in their physiological reactivity. Boyce and Ellis have written about two types of children (i.e., two temperaments), dandelions and orchids, those who can grow anywhere and those who need heightened care and attention in order to flourish (Ellis & Boyce, 2008). Boyce's work focuses specifically on individual differences in autonomic or stress reactivity (via the hypothalamic-pituitary-adrenal [HPA] system) and the role that environments have in leading to either negative or optimal outcomes (Boyce *et al.*, 1995). The closest this work has come to traditional notions of temperament is the work on difficult temperament or negative emotionality, usually measured via caregiver report, and the findings that children with negative or difficult temperaments do more poorly in harsh environments but in some instances thrive and have optimal outcomes under supportive environments. For example, Van Aken *et al.* (2007) showed that 16- to 19-month-old boys with difficult temperament had the lowest levels of externalizing behavior with highly sensitive caregiving but the largest levels with insensitive caregiving. These studies support the differential susceptibility model but the links between those using candidate genes and those examining temperament differences have yet to be established.

Finally, the recent advances in epigenetics (see Chapter 25) provide some promise for understanding how individual differences may be transmitted across generations. Reactivity to specific types of novel stimuli may be a product of the experiences of prior generations and influence subsequent infant reactivity. A recent study by Dias and Ressler (2013) illustrates this epigenetic transmission in a mouse model. Mice were aversively conditioned to an odor and subsequent generations (based apparently on methylation processes at the level of gamete) came to react sensitively to these same odors. This may hold promise for understanding at least some of the variability in individual differences in infant reactivity.

The temperament of behavioral inhibition

As mentioned, Jerome Kagan was the first to describe the temperament of behavioral inhibition, and this work substantively changed the clinical and research approach to temperament, for many reasons. First, Kagan used careful behavioral description, often instead of maternal report, to study temperament. Second, he assessed physiological markers and emphasized

stability of both physiology and behavior. And third, he linked his work to neuroscientific studies of fear, thus providing a basis for thinking about this temperament as a model system for understanding the origins of anxiety. Behavioral inhibition refers to a child's temperamental profile characterized by initial negative emotional and motor reactivity to novelty during infancy (Kagan *et al.* 1984) and tendency in later childhood to display fearful or withdrawn behavior when confronting unfamiliar events, objects, or people (Rothbart & Alansky 1990; Kagan & Snidman 1991; Fox *et al.*, 2005). Behavioral inhibition has an associated physiologic profile, reflected in high heart rate and low-heart rate variability, elevated cortisol secretion, pupil dilation, increased startle response, and right frontal electroencephalographic (EEG) asymmetry (Kagan *et al.*, 1987; Bell & Fox, 1994; Calkins *et al.*, 1996; Lopez *et al.*, 2004; Pérez-Edgar *et al.*, 2008; Reeb-Sutherland *et al.*, 2009). Kagan (2001) proposed that this physiology arose from perturbations in the amygdala, extending work at the time in rodents (Davis, 1986; LeDoux *et al.*, 1988). While this underlying circuitry is undoubtedly complex, interesting cross-species parallels do exist (Pérez-Edgar & Fox, 2005).

There is modest continuity to the temperament of behavioral inhibition. Pérez-Edgar and Fox (2005) report correlations between the ages of 1 and 6 years in the 0.24–0.64 range, with greater stability found among extreme groups. And, across studies children who maintain this disposition are at higher risk for developing an anxiety disorder (Hirshfeld *et al.*, 1992; Turner *et al.*, 1996; Kagan & Snidman, 1999; Prior *et al.*, 2000; Biederman *et al.*, 2001; Chronis-Tuscano *et al.*, 2009). A recent meta-analysis quantifies this association as large in magnitude (Clauss & Blackford, 2012). Nevertheless, half or more of behaviorally inhibited children will not have anxiety disorders in adolescence, suggesting moderation by endogenous and exogenous factors. Degnan and Fox (2007) suggest that these include parenting behaviors and various information-processing functions of the child. One type of parenting style associated with behavioral inhibition is overprotective control or oversolicitous parenting (Rubin *et al.*, 2002). This parenting style is composed of behaviors such as intrusiveness and limiting of the child's opportunity for autonomy (Rubin *et al.*, 1997). For instance, a history of high behavioral inhibition (BI) is associated with symptoms of social anxiety during adolescence, only in the presence of high maternal overcontrol observed during childhood (Lewis-Morrarty *et al.*, 2012).

Peers provide an additional source of socialization, beginning as early as infancy, and continuing as children spend more time at school and in extracurricular activities (see Hay *et al.*, 2009). Indeed, early exposure to different childcare environments during infancy and toddlerhood may have a profound influence on the developmental trajectory of behavioral inhibition. Research has shown that children's relationships with peers can influence the stability of withdrawn or inhibited behavior during the preschool years (Furman *et al.*, 1979), early childhood (Gazelle & Ladd, 2003), and middle childhood (Booth-LaForce &

Oxford, 2008). Fox and colleagues (2001b) found positive effects of childcare on the stability of behavioral inhibition. Children with this temperament placed into peer-oriented day care were less likely to display stable behavioral inhibition over age. This pattern was replicated in an independent sample of infants placed into peer day care. These studies suggest that exposure to peer interactions in childcare settings fosters the development of competent social skills among behaviorally inhibited children. This exposure moderates the temperament of behavioral inhibition and decreases the likelihood of social withdrawal at later ages among this temperament group (Degnan & Fox, 2007).

Temperament and adjustment

Researchers have found that behaviors reflecting different temperamental dispositions such as positive emotionality, irritability, sociability, avoidance, and negative affect are related to adaptive and maladaptive outcomes across development. Positive emotionality, which is a core behavior in the temperament of exuberance, is positively associated with social competence as well as social behavioral problems (Eisenberg *et al.*, 2009; Hayden *et al.*, 2006). Avoidance and negative reactivity, which are core behaviors in the temperament of behavioral inhibition, are related to social reticence and anxious symptoms (Fox *et al.*, 2005).

Studies suggest that heightened motor reactivity and negative affect and behavioral inhibition are associated with, and predictive of, internalizing problems later in childhood and adolescence (Asendorpf, 1991; Fox *et al.*, 2005). Behaviorally inhibited children, as they get older and are exposed to peer situations, may develop anxiety, loneliness, depression, negative self-perceptions of their social competencies, and other internalizing problems (e.g., Coplan *et al.*, 2004; Fox *et al.*, 2005; Kagan *et al.*, 2007). Kagan and colleagues found that adolescents who were high-reactive in toddlerhood displayed higher levels of social anxiety than those who were low-reactive (Schwartz *et al.*, 1999). Chronis-Tuscano *et al.* (2009) reported that infants and young children who displayed stable behavioral inhibition across early childhood had an increased risk for developing anxiety disorders, particularly social anxiety. And a recent meta-analysis (Clauss & Blackford, 2012) reported a moderate effect size across studies of behavioral inhibition in risk for anxiety disorders. Taken together, several large-scale longitudinal projects have provided convergent evidence that highly reactive and shy-inhibited children are likely to develop internalizing socioemotional problems, such as social anxiety and life dissatisfaction, in adolescence and adulthood. Moreover, these children, particularly boys, tend to experience difficulties in later social relationships and life adjustment (Caspi *et al.*, 2003).

In addition to temperamental behaviors identified in infancy (such as reactivity), behaviors that underlie an individual's ability to regulate their own behavior are both thought of as

reflecting temperament and are associated with adjustment later in life. These behaviors, emerging as they do over the preschool period (attention shifting, inhibitory control), are often referred to under the heading of "effortful control." In general, such behaviors facilitate children's ability to behave appropriately across a wide range of contexts (Kochanska *et al.*, 2000; Eisenberg *et al.*, 2009; Rueda, 2012). Longitudinal research suggests that effortful control in early childhood is related to later adjustment (Eisenberg *et al.* 2009). For example, Eisenberg *et al.* (2009) found that parent and teacher ratings of low attentional (maintaining or shifting attentional focus according to the task) and low inhibitory (suppressing inappropriate responses) control was associated with externalizing problems in middle childhood. Moreover, low effortful control was associated with an increase in externalizing problems over time.

Caspi and colleagues (2003), with data from the Dunedin study, found that undercontrolled children displayed social and behavioral problems, such as perceived alienation from the world and aggression, in adulthood. Children with undercontrolled temperament were also more likely than well-adjusted children to engage in disordered gambling as adults (Slutske *et al.*, 2012). And Moffitt *et al.* (2011) described relations between childhood self-control and adulthood health, wealth, and public safety in the Dunedin sample.

Although the broad construct of effortful control has been found to be negatively correlated with negative affect including symptoms of anxiety, when inhibitory control and attention shifting were examined separately, their contribution to the regulation of negative reactivity was distinct from one another. For example, behaviorally inhibited children with high levels of inhibitory control were less socially competent, more socially withdrawn, and reported as being more socially anxious than BI children with low levels of inhibitory control (Fox & Henderson, 2000; Thorell *et al.*, 2004; White *et al.*, 2011). Furthermore, high levels of inhibitory control at age 4 increased the risk for anxiety problems in the preschool years amongst children who were high in behavioral inhibition at age 2, whereas high levels of attention shifting at age 4 decreased the risk for preschool anxiety problems in these children (White *et al.*, 2011).

The paradoxical role of cognitive control in relation to temperamental reactivity is seen best within the literature on error monitoring. Figure 8.2 depicts procedures for monitoring this construct. Error monitoring is often measured by examining response times on trials following an error as compared to response times following correct trials. If inaccurate performance is particularly salient to an individual, more controlled and slower responding in the trial following an error is typically exhibited (Davies *et al.*, 2004). Such behavioral measures can also be supplemented with psychophysiological indices, such as an event-related potential known as the error-related negativity (ERN). The ERN is a specific neural activity pattern associated with cognitive monitoring that is usually observed between 50 and 150 ms post response after the commission of an error and has a centromedial scalp distribution (Falkenstein *et al.*,

Figure 8.2 Assessment of error monitoring using the Erikson Flanker Task (Eriksen & Eriksen, 1974). The subject's task is to press a button indicating the direction of an arrow in the center of the computer screen. That arrow can be "flanked" by arrows in the same direction or in different directions. During the task, brain electrical activity is recorded and synchronized to the subject's button press. On trials where the subject makes an error an event-related potential (ERP) is generated, called the error-related negativity (ERN).

1991; Gehring *et al.*, 1993; van Veen & Carter, 2002). It appears that error monitoring is heightened in patients with anxiety disorders. Gehring and colleagues (2000) found a heightened ERN in subjects with obsessive compulsive disorder (OCD). Other investigators extended this to other anxious groups (Weinberg *et al.*, 2010; Meyer *et al.*, 2012), as supported in a recent meta-analysis (Moser *et al.*, 2013).

Similar findings manifest in behavioral inhibition (Henderson, 2010). For example, McDermott *et al.* (2009) found the ERN to be larger for adolescents who were characterized with high behavioral inhibition in childhood as compared to adolescents low on childhood behavioral inhibition. In addition, the ERN moderated the relations between early behavioral inhibition and later anxiety disorders during adolescence, such that for those participants high on behavioral inhibition, larger ERNs were related to higher risk of anxiety disorders (McDermott *et al.*, 2009). This pattern of relation between temperament and error monitoring was replicated and extended in an independent sample by Lahat and colleagues (2014). Seven-year-old children who were characterized in infancy with behavioral inhibition were assessed for ERN and symptoms of anxiety were measured via an anxiety scale at age 9. Lahat found first that children

with a history of behavioral inhibition showed heightened ERN amplitudes and, second, that the magnitude of the ERN moderated the link between temperament and anxiety symptoms. Children with the temperament of behavioral inhibition who also had larger ERN amplitude (greater error monitoring) were more likely at age 9 to have more symptoms of anxiety.

Behavioral inhibition: temperament or psychopathology?

Behavioral inhibition may be one of the best and well characterized of child temperaments for understanding the etiology of at least some forms of anxiety. By itself it conveys a heightened risk for anxiety disorders and particularly social anxiety. But that risk is tempered by both the effects of environmental manipulations (caregiving context and behaviors) as well as intrinsic factors such as attention and cognitive control processes. For example, Fox *et al.* (2001b) reported that infants characterized as high-reactive who were placed into peer-oriented day care were less likely to exhibit behavioral inhibition during childhood.

This effect of early caregiving context on temperament was replicated in an independent sample, again demonstrating the effects of environmental manipulations on temperament (Almas *et al.*, 2011).

The interrelations between temperament and psychopathology have led to discussions about the very nature of this temperament and whether the behaviors described as reflecting behavioral inhibition are merely a prodromal manifestation of anxiety. Considerable work examines differences between behavioral inhibition and anxiety (Rapee, 2002; Pérez-Edgar & Fox, 2005). As noted earlier, there are both similarities and differences in these two constructs (see Rapee, 2002; Pérez-Edgar & Fox, 2005). Developmentally, the two constructs appear more distinct than similar. There are a number of reasons to think that this is the case. First, anxiety is usually associated with cognitive rumination, while behavioral inhibition, assessed in infancy and early childhood, is not. Behavioral inhibition is identified early in the first years of life when it is unlikely that ruminative processes are involved. Second, temperamental behavioral inhibition in the early years of life is highly plastic. It is unlikely that anxiety at any period is as malleable. On the other hand, behavioral inhibition is associated with social reticence (observable during the preschool and school years), which is associated with anxious behaviors and cognition such as low self-esteem. Third, perhaps best summarized is the notion that the temperament of behavioral inhibition is reflected in general cautiousness, while anxiety focuses on worry and often specific fears. And fourth, importantly, using self and parent report measures, the overlap between report of behavioral inhibition and anxiety is not high (correlations ranging from 0.3 to 0.6). The most illuminating studies on this topic have been conducted by Rapee (Rapee *et al.*, 2005). He developed a parent-centered intervention for children at risk for anxiety and recruited children with the temperament of behavioral inhibition for such efforts. In one intervention program, behaviorally inhibited preschool children were selected on the basis of maternal report and observations of high levels of inhibition/withdrawal and assigned to either a parent education program or a monitor condition in which they did not receive any intervention (Rapee *et al.*, 2005). Findings indicated that children in the intervention condition showed a decrease in anxiety disorders approximately 12 months after the intervention compared to children in the monitoring condition (Rapee *et al.*, 2005). However, there were no differences between the intervention and control groups on behavioral inhibition one year later. Furthermore, results of a 3-year follow-up indicated that children assigned to the parent education condition during preschool were less likely to develop anxiety disorders or report symptoms of anxiety compared to children in the monitoring condition during middle childhood (Rapee *et al.*, 2010). Again, the intervention continued to have no impact on parent report of the child's temperament, as behavioral inhibition was found to decrease over time regardless of the intervention group (Rapee *et al.*, 2010). These findings suggest that anxiety and the temperament of BI may in fact be separable constructs.

The question before clinicians and parents is whether prevention programs like the one described by Rapee (2013) should be uniformly applied to all children with the temperament of behavioral inhibition. The intervention appears to work and is short in duration. However, most young children with the temperament of behavioral inhibition will not develop anxiety disorders; therefore, administering a prevention/intervention to them may end up being counterproductive. It is the case that many parents of shy reticent children, particularly young boys, are concerned about their child's behavior. Such parents should be provided with information on how to parent their shy reticent child as well as the importance of valuing individual differences in their young children. It may, however, be unnecessary to implement, on a widespread basis, a prevention program for a common temperament, such as behavioral inhibition, that is associated with one type of important individual difference in approaching the world.

Future directions in temperament research

The field of temperament research has brought to the forefront the importance of individual differences when considering the trajectories of social development of young children. There are, no doubt, many different temperament types, each with its unique set of behavioral responses to stimuli in the environment. In particular, there is growing interest in the temperament of exuberance, with research in this area holding great promise.

Temperamental exuberance

Positive reactivity to novelty may be as robust a temperamental construct as avoidance and negative reactivity. There are a number of studies showing associations between individual differences in positive reactions to novelty (approach behavior) in infancy and related to child social-emotional outcomes. Infants who display positive affect and motor reactivity to novel stimuli are more likely to show uninhibited, exuberant, and sociable behavior in infancy (Putnam & Stifter, 2002; Hane *et al.*, 2008) and toddlerhood (Calkins *et al.*, 1996; Park *et al.*, 1997; Fox *et al.*, 2001b; Putnam & Stifter, 2005). In addition, a combination of high positive affect and approach behavior is associated with impulsivity, positivity, and sociability in childhood (Fox *et al.*, 2001a; Pfeifer *et al.*, 2002; Stifter *et al.*, 2008).

In the developmental literature, terms such as positive affectivity, surgency, extraversion, approach reactivity, impulsivity, and sensitivity to reward are often used to describe exuberant temperament (Polak-Toste & Gunnar, 2006; Rothbart & Bates, 2006). Fox and colleagues described a subset of their infant sample as approaching novelty and enjoying social interaction, and suggested links to fearlessness, risk taking, and social competence (Fox *et al.*, 2001a; Hane *et al.*, 2008). Goldsmith and colleagues described their childhood sample in terms of increased positive affect and a heightened, fearless approach to novel stimuli (Pfeifer *et al.*, 2002). In general, positive affect

has been posited as the core, distinguishing factor involved in exuberance, surgency, or extraversion (Watson & Clark, 1997; Rothbart *et al.*, 2001; Putnam & Stifter, 2005).

There are clear distinctions between the temperaments of behavioral inhibition and exuberance. For instance, one study examining measures of both behavioral inhibition and exuberance across childhood showed nonlinear relations between them, where high exuberance was predicted by average levels, as opposed to low levels, of behavioral inhibition (Pfeifer *et al.*, 2002). In addition, Putnam and Stifter (2005) described multiple types of behavior, based on levels of approach and positive or negative affect, where low approach combined with negative affect reflected behavioral inhibition and high approach combined with positive affect reflected exuberance. More work is needed to define the underlying neural circuitry and physiological reactions of temperamental exuberance. But it is an area where there is great interest and novel findings are awaited.

Final comments

After the birth of their first child, most parents believe that they can mold or shape that child's behavior as they parent their child toward development. Ask parents after they have had their second child and no doubt they will tell you of the individual differences they see between their first and second child and how their child is as much a determinant of the caregiving environment as their own perceptions and beliefs. Temperament continues to exert its influence across different developmental phases. In childhood, temperament reciprocally shapes individuals' perceptions of their surroundings, including responses to peers and acceptance into the peer group. And no doubt, in adolescence, temperament influences an individual's choice of social network, thus playing an important role in determining the extent and direction of adolescent peer influences and the impact of these on later social and mental health outcomes. Individual variation in response to the environment is what produces the richness and complexity of culture and society. The study of temperament, its underlying biology, and the manner in which it shapes trajectories of development contributes significantly to our understanding of the variation in human behavior.

B: Neurobiology

CHAPTER 9

Neurobiological perspectives on developmental psychopathology

Mark H. Johnson

Centre for Brain and Cognitive Development, School of Psychology, Birkbeck College, University of London, UK

Introduction

The brain is an organ of adaptation at multiple time scales. Over evolutionary time, our brain has become adapted in various ways to construct and occupy the niche of our species. In ontogeny (individual development), our brain adapts both to the general features of our environment shared with others, and to the individual circumstances into which we are born. Further, on a scale of days and hours, we can learn and retain information of survival relevance through processes of learning and attention. On the scale of seconds and milliseconds, our neural processes adapt to current sensory input and change state or prepare motor responses. While we can marvel at the complex and dynamic processes that underlie these adaptations, it is not surprising that there are also many different ways for them to go awry.

The brain is also an organ of adaptation at multiple levels of organization. Neuroscience is one of the broadest interdisciplinary fields in biology, spanning from complex molecular interactions, through intra- and intercellular processes, to the emergent computations that result from many thousands of neurons coherently oscillating in their firing patterns. In this chapter I review perspectives on human developmental psychopathology that arise from consideration of theories and evidence from developmental neurobiology. In some respects it seems obvious that the underpinning basic science of the human brain must be relevant to issues in developmental psychopathology. However, in other respects it is less clear that complex mental and behavioral problems can be understood by reducing these phenomena to cellular or neurochemical processes. In what follows we see that the consideration of the underlying neurobiology can benefit developmental psychopathology in several ways. First, assumptions and debates in developmental neurobiology often reflect those at a “higher”

level of observable and as such can be informative. Second, the advent of new neuroimaging and genetic methods make a closer integration between the two fields inevitable. Third, it is possible to integrate data from multiple levels of observable in nonreductionist ways that can enhance our understanding of neurocognitive development and the ways that this can go awry in development.

Neurobiology is a broad field that spans multiple levels from molecular and genetic analyses, through cellular level studies, to the study of neural systems and pathways and how these relate to cognitive functions and behavior. We see in what follows that key issues about plasticity, timing, and constraints on development are often reflected in specific debates within the domains of genetics, cellular studies, and neural and cognitive systems.

Key issues in developmental neurobiology

Deterministic versus probabilistic epigenesis

The study of development necessarily implies an interdisciplinary approach in which the relevant pathways from genotype to phenotype are characterized. Gottlieb (1992) distinguished between two different approaches to the study of developmental biology; “deterministic epigenesis” in which it is assumed that there is a unidirectional causal path from genes to structural brain changes to psychological functions, and “probabilistic epigenesis” in which interactions among genes, structural brain changes, and psychological function are viewed as bidirectional, dynamic and emergent. While most would agree with the latter approach when presented in this explicit way, the former view still underpins basic assumptions that remain widespread in our field. For example, it is common in the literature to see claims about particular regions of the human cerebral cortex “coming on-line” at specific ages, with the implication that this is a

deterministic process. However, recent advances have revealed how complex context-dependent patterns of expression are the order of the day. In other words, the development of the brain is best viewed as an active self-organizing process involving interactions between genes and their current context, and not as the passive unfolding of a genetic blueprint on a strict maturational timetable.

Mosaic versus regulatory development

In many simpler organisms (such as the nematode *C. elegans*), development proceeds through cell lineages that are largely independent of each other, a process described as “mosaic” (Elman *et al.*, 1996). A cell will divide to yield other more specialized cells along a progression or lineage that is largely uninfluenced by the surrounding context or by other neighboring cells. In contrast, the construction of the brain in vertebrates is better characterized as following a “regulatory” developmental process. In other words, the division of cells to yield more specialized descendants is dependent on the current context, including the presence or absence of other cells of similar or dissimilar types.

These contrasting mechanisms at the cellular developmental level can also inform our thinking about the development of whole brain regions in humans. For nearly two decades, functional imaging studies in human adults were dominated by the search for the specific cortical regions said to be responsible for particular perceptual, cognitive or linguistic functions (“the region for X”, where X is a cognitive or perceptual function). In contrast, over the past decade, the view has emerged that the response properties of a particular brain region are largely determined by its patterns of connectivity to other regions as well as by their current activity states (Friston & Price, 2001).

Extending these different approaches to neurodevelopment, it remains a common assumption that the maturational timetable of specific brain regions is largely independent of those of its connectivity neighbours. In contrast to this, at least one domain-general framework for studying human functional brain development (Interactive Specialization (IS), see later section) is based on the opposing assumption that interactions between brain regions are critical for the development of each one, and that networks of regions give rise to emerging functions as a coherent whole.

Static versus dynamic mapping

The assumption that different brain regions are a mosaic of isolated computational units encourages the view that structure–function relations in the brain are static and unchanging. In the context of typical development, this leads to the view that different regions can mature independently of other regions according to their own particular intrinsic timetable, and that developmental disorders could be due to deficits in specific regions. The “static assumption” is partly why it is sometimes considered to be acceptable to study developmental disorders in adulthood and then extrapolate back in time to early development. Contrary to this view, recent evidence suggests

that when a new computation or skill is acquired, there is a reorganization of interactions between different brain structures and regions (Johnson, 2011). This reorganization process may even change how previously acquired cognitive functions are represented in the brain. Thus, different networks of regions can often support the same overt behavior at different ages during development.

Plasticity, epigenetics, and fate maps

The development of biological structures, such as the brain and its constituent parts, is often considered as a process of “restriction of fate.” This notion comes from the observation that as development unfolds, increasingly more complex types of cells and specialized structures emerge. However, these are assumed to be just one of the possible outcomes latent in the original stem cells. Indeed, we know this to be the case, as transposing the location of a group of cells within the developing embryo will often cause the cells to form a different structure from that which they would have done originally. The fact that some stem cells can generate multiple different types of tissue is the basis for recent advances in medical science and psychiatry. Underpinning this cellular level plasticity are processes of gene expression (see Chapter 24).

The rapidly evolving field of human genetics has moved from the traditional notion of a “blueprint” that unfolds in a series of predetermined steps, to a view of the human genome as being open to a variety of factors that influence the degree of expression of different genes at different developmental points. For example, we now know that the lifelong expression of genes in individual animals can be regulated by the animal’s early environment. For example, maternal behavior toward newborn rats regulates the expression of genes involved in the same rats’ responses to stress later in life (Weaver *et al.*, 2004). Thus, early sensory experiences can have lifelong effects through permanent changes in the timing and amount of different proteins expressed by the genes. Work such as this has led to the newly emerging field of “epigenetics” (Chapter 25).

At first sight, the role of epigenetic processes in the construction of a human brain seems under-constrained. Given these deep and powerful mechanisms of latent plasticity, what factors constrain patterns of expression of the genome to give sufficient “stability” in order that the complexity and structure of the human brain results? This key question is currently the focus of much research and a number of factors that constrain the epigenome are beginning to be described. Recent papers have described some of the complexity and dynamics of gene expression derived from developing and adult post mortem human brains (Colantuoni *et al.*, 2011; Kang *et al.*, 2011). Ninety percent of the brain-related genes analyzed were differentially regulated across either different brain regions or points in developmental time. The majority of this differential expression occurred during prenatal development, with patterns of expression tending to become more fixed with increasing age (Kang *et al.*, 2011).

One mechanism that promotes stability within the dynamic epigenome is genomic imprinting. This is a process through which certain genes (less than 1% in mammals) are expressed according to the parent of origin of that variant of the gene. Effectively, genomic imprinting silences the allele from either the mother or the father, leaving the remaining one to be exclusively expressed. These epigenetic marks are present from the outset of an embryo and can be maintained throughout the lifespan. Some developmental disorders, such as Angelman syndrome and Prader–Willi syndrome are associated with deficits in this process (see Chapter 54).

Plasticity in brain development is a phenomenon that has generated much controversy, with several different conceptions and definitions having been presented. Sometimes plasticity is invoked in a specialized series of mechanisms that are activated following brain injury. However, in development we can simply view plasticity as the state of a brain region's structure or function not yet fully specialized. That is, there is still remaining scope for developing more finely tuned neural architecture or responses. By this view the mechanisms of plasticity remain the same throughout the lifespan, but the expression of plasticity is more limited in adulthood because most aspects of brain structure and function have already become specialized, and thus there is less scope for further change. Plasticity is thus the flip side of the coin of "restriction of fate."

The role of time in brain development

The brains of all mammals follow a basic vertebrate brain plan that is found even in species such as salamanders, frogs, and birds. Despite the evolutionary continuity in this basic plan, one of the major differences between these species and higher primates is in the dramatic expansion of the overlying cerebral cortex, together with associated structures such as the basal ganglia. This raises the question of what is unique about the human brain and the developmental processes that give rise to it (and, relatedly, how applicable are studies on other species to our understanding of human brain development).

As a first approximation, across different species, brain size correlates with both body size and the length of developmental time it takes to reach its adult size. As large mammals, primates generally have a much more prolonged timetable for brain development than other mammals. Even between *Homo sapiens* and other primates there is a wide difference in timing. In particular, our species' period of postnatal cortical development is extended by roughly a factor of four compared to most other primates. What is the significance of this extended timetable of brain development?

Finlay and Darlington (1995) compared data on the size of brain structures from 131 mammalian species, and concluded that the relative order of landmarks of brain development is widely conserved. Further, even controlling for overall brain and body size, the time course of these landmarks is related to the relative size of structures of the adult brain in a systematic way and that disproportionately large growth occurs in the later

generated structures. From this analysis, the structure most likely to differ in size in the comparatively slowed timetable of neurogenesis in primates is the neocortex.

It seems likely that the increased quantity of cortical tissue in our brains is at least, in part, a by-product of still further slowing down of the overall mammalian time course of brain development (but see Dehay & Kennedy, 2009). This suggests that evidence from other mammals will be highly relevant to the study of human brain development since we are looking at fundamentally the same process, albeit unfolding on a larger scale and a prolonged timetable. In addition to differences in the overall rate of brain development, however, different mammalian species are born at different stages of brain development. In this regard, while humans have the survival disadvantage of being born relatively immature and largely immobile, the highly prolonged period of postnatal development allows much more scope and time for interaction with the social and physical environment of the child to contribute to the tuning and shaping of circuitry. Viewed from this perspective, the high importance of parent–infant bonding and interaction as part of the constructed niche of our species becomes evident (Atzil *et al.*, 2012).

Whether it is just the slowed timing of brain development that produces the unique human brain remains controversial. Subtle differences in the steps of cortical development between primates and rodents are already known, and some reports of possibly species-specific progenitor cells or neurons in humans merit further research (Bystron *et al.*, 2008). It is also clear that sequence differences in the noncoding, regulatory regions of the genome likely account for many of the differences across primate species (Kang *et al.*, 2011).

Human structural brain development

The sequence of events involved in the prenatal development of the human brain closely resembles that of many other vertebrates. After initial divisions of the fertilized cell, a cluster of proliferating cells (called the blastocyst) differentiates into a three-layered structure (the embryonic disk) with each of these layers further differentiating into major organ systems. The outer layer (ectoderm) gives rise to the nervous system through a process known as *neurulation*. Specifically, a portion of the ectoderm begins to fold in on itself to form a hollow cylinder called the *neural tube*, which then differentiates further to give rise to the major subdivisions of the central nervous system, with the forebrain and midbrain arising at one end and the spinal cord at the other. One end differentiates into a series of repeated units or segments to become the spinal cord, while at the other end of the neural tube a series of bulges and convolutions form. Around 5 weeks after conception in humans these bulges can be identified as protoforms for the cortex (telencephalon), the thalamus and hypothalamus (diencephalon), the midbrain (mesencephalon), and others to the cerebellum (metencephalon) and to the medulla (myelencephalon).

Differentiation within these different bulges gives rise to the complex layering patterns and cell types found in the adult brain. Within these bulges, cells *proliferate* (are born), *migrate* (travel), and *differentiate* (change form) into particular types. The vast majority of the cells that will compose the brain are born in the so-called *proliferative zones*. These zones are close to the hollow portion of the neural tube (which subsequently become the ventricles of the brain). The first of these proliferation sites, the *ventricular zone*, may be phylogenetically older (Nowakowski, 1987). The second, the *subventricular zone*, only contributes significantly to phylogenetically recent brain structures such as the neocortex (i.e., “new” cortex). These two zones yield separate glial (support and supply cells) and neuron cell lines and give rise to different forms of migration.

Neurons and glial cells are produced within these zones by division of cells to produce clones (a clone is a group of cells produced by division of a single precursor cell—such a precursor cell is said to give rise to a lineage—see earlier section). *Neuroblasts* produce neurons, and in some cases particular neuroblasts also give rise to specific types of cell. For example, less than a dozen proliferating cells produce all the Purkinje cells of the cerebellar cortex, with each producing around 10,000 cells (Nowakowski, 1987).

A striking new hypothesis is that during evolution nature has capitalized on certain kinds of mutations that occur when cells divide in order to increase the diversity of types of neurons that can be generated (Muotri & Gage, 2006). The argument is that by incorporating somatic mutational mechanisms into development, the variety of different types of neurons that can be produced is much greater. To assess this idea, Evrony *et al.* (2012) developed a method to amplify the genomes of single neurons from human post mortem cerebral cortex and caudate nucleus. In doing so, they found that most neurons lacked the predicted somatic insertions, suggesting that at least one type of mutation is not a major generator of neuronal diversity in typical development. However, this approach remains potentially fruitful for investigating disorders of development at the cellular level, particularly if lack of neuronal diversity is a characteristic of the condition.

After young neurons are born, they *migrate* from the proliferative zones to the particular region where they are located in the mature brain. The first and more common type of migration is *passive cell displacement*. This occurs when cells that have been generated are then simply pushed further away from the proliferative zones by more recently born cells. This form of migration gives rise to an “outside-in” pattern, with the oldest cells being pushed toward the surface of the brain, while the most recently produced cells remain closer to their place of birth. Passive migration gives rise to brain structures such as the thalamus, the dentate gyrus of the hippocampus, and parts of the brain stem.

The second form of migration is more active and involves the young cell moving past previously generated cells to create an “inside-out” pattern. This pattern is found in the cerebral cortex

Figure 9.1 The radial unit model of Rakic (1988). Radial glial fibers span from the ventricular zone (VZ) to the cortical plate (CP) via a number of regions: the intermediate zone (IZ) and the subplate zone (SP). RG indicates a radial glial fiber, and MN a migrating neuron. Each MN traverses the IZ and SP zones that contain waiting terminals from the thalamic radiation (TR) and corticocortical (CC) afferents. As described in the text, after entering the cortical plate, the neurons migrate past their predecessors to the marginal zone (MZ). Source: Reprinted with permission of Wiley.

and in other areas that have a laminar structure (divided into parallel layers). In the case of the cerebral cortex, a “radial unit model” of neocortical differentiation gives an account of how both the layered and the regional structure of the mammalian cerebral cortex arises (Rakic, 1988). According to the model, the laminar organization of the cerebral cortex is determined by the fact that each proliferative cell (in the subventricular zone) gives rise to approximately 100 neurons. The progeny from each proliferative cell all migrate up the same route, with the latest to be born travelling past their older cousins. The route they take is determined by following a radial glial fiber—a long process that stretches from the top to the bottom of the cortex and originates from a glial cell. These radial glial fibers act like a guidance rope to help ensure that cells produced by one proliferative unit all contribute to one radial column within the cortex (see Figure 9.1).

While the “radial unit model” explains how cortical cells arrange themselves into the (approximately 100 neuron) thickness of the cortex, how does the differentiation into specific layers emerge? While we are far from being able to answer this question definitively at this point, in some cases differentiation

into particular cell types occurs *before* each neuron reaches its final location. However, in other cases some of the properties that distinguish among cell types may only form later. For example, the distinctive apical dendrite of pyramidal cells, which often reaches into the upper layer of the cortex (layer 1), is a result of the increasing distance between this layer and other layers resulting from the inside-out pattern of growth (Marin-Padilla, 1990).

It has recently become apparent that not all migration within the cortex follows the radial unit model (Polleux *et al.*, 2002). Interspersed between pyramidal cells are a variety of types of interneurons that help balance excitation and inhibition within the cortex. Several psychiatric disorders, such as autism and schizophrenia, are thought to involve dysregulation of this balance (Le Blanc & Fagiolini, 2011; Lewis *et al.*, 2012), and in some cases this may be due to differences in the molecular mechanisms known to control tangential migration processes (Polleux *et al.*, 2002).

By the time of birth in humans, the vast majority of neurons have been born, migrated to their final locations and have differentiated into recognizable types. The main lobes and sulci of the cortex are also developed. Nevertheless, a considerable portion of human brain development continues into postnatal years.

Key features of postnatal development

As mentioned earlier, key features of human brain development are its comparatively prolonged time schedule, and the relatively immature point on the sequence of development at which we are born. These factors combine to allow for a greatly extended period of postnatal brain development in relation to most other mammals, and a correspondingly large increase in the total volume of the brain from birth to teenage years. Since the formation of neurons and their migration to appropriate brain regions takes place almost entirely within the period of prenatal development in the human, these do not account for the increase in volume. However, there is a dramatic postnatal increase in size and complexity of the dendritic tree of most neurons. While the extent and reach of a cell's dendritic arbor may increase dramatically, its patterns of connectivity with other cells also become more specific. Huttenlocher and colleagues have reported a steady increase in the density of synapses in several regions of the human cerebral cortex (Huttenlocher *et al.*, 1982; Huttenlocher, 1990, 1994). While an increase in synapses (synaptogenesis) begins around the time of birth in humans for all cortical areas studied to date, the most rapid bursts of increase, and the final peak density, occur at different ages in different areas. In the visual cortex there is a rapid burst at 3–4 months, and the maximum density of around 150% of adult level is reached between 4 and 12 months. In contrast, while synaptogenesis starts at the same time in a region of the prefrontal cortex (PFC), density increases much more slowly and does not reach its peak until well after the first year (see Figure 9.2).

Similar “rise and fall” patterns of development have been observed in other measures of human brain development. For example, using PET imaging, Chugani *et al.* (2002) measured overall resting brain metabolism (the uptake of glucose from the blood is essential for cell functioning) in early postnatal development. They observed a sharp increase in glucose uptake followed by a later decline; with a peak approximately 150% above adult levels achieved somewhere around 4–5 years of age for some cortical areas. While this peak occurred somewhat later than that in synaptic density, an adult-like *distribution* of resting activity within and across brain regions was observed by the end of the first year.

While the developmental events discussed so far concern aspects of the structure of the brain, it is important to note that there are also significant changes in the “soft soak” aspects of neural function, molecules involved in the transmission and modulation of neural signals. A number of neurotransmitters in rodents and humans also show the rise and fall developmental pattern (see Benes, 1994, for review). For example, the excitatory intrinsic transmitter glutamate, the intrinsic inhibitory transmitter GABA (Gamma-aminobutyric acid), and the extrinsic transmitter serotonin all show this same developmental trend. Thus, the distinctive “rise and fall” developmental sequence is seen in a number of microscopic and metabolic measures of structural and neurophysiological development in the human cortex.

In contrast to the rise and fall pattern, other aspects of postnatal human brain development such as myelination show a steady increase (Figure 9.2). In the central nervous system, sensory areas tend to myelinate earlier than motor areas. Cortical association areas are known to become myelinated last, with the process continuing into the second decade of life. Because myelination is a prominent feature of postnatal development, there has been much speculation linking it to advances in behavioral and cognitive development. However, while myelination greatly increases the speed and fidelity of transmission of impulses (by as much as 100 times), it is also important to remember that under-myelinated connections in the young human brain are still capable of transmitting signals, and that some connections in the adult brain never myelinate.

Recently, MRI methods have come to the fore in studying the structural development of the brain at a larger scale. MRI reveals brain structure at a more gross scale than neurons and synapses, but sufficient to allow the measurement of gray and white matter in different cortical and subcortical regions. One report described cortical gray matter development in participants from 4 to 21 years (Gogtay *et al.*, 2004). The authors report considerable heterogeneity between different individuals, and between different cortical regions. Nevertheless, they confirmed that cortical gray matter shows the characteristic “rise and fall” pattern described above, and indicates the pruning or elimination of excess connections between neurons. For some cortical regions most of the rise occurs before puberty, and most of the decline after puberty going into early adulthood.

Figure 9.2 An approximate timeline for some of the most important changes in human brain development. *Source:* Reprinted with permission of Elsevier.

Also, broadly consistent with earlier reports based on post mortem neuroanatomical studies, the authors observed that the primary sensory areas of the cortex, along with the frontal and occipital poles, show the fastest growth (and decline) curves.

Most of the remainder of the cortex develops in an approximately back-to-front direction, with the PFC showing the most delayed developmental curve. However, the posterior superior temporal cortex, which is a critical part of the social brain network and integrates information from different sensory modalities, develops last according to this particular measure. Similar MRI data have been collected for the volume of white matter (myelinated fiber bundles), and this shows a general linear increase with age through to early adulthood. The lack of a later decline in this measure may reflect the ongoing life-long myelination of fibers that adds to the overall volume of the brain.

Overall, a number of different measures and laboratories have found the rise and fall pattern for neurons and their local connectivity. However, it should be noted that measures such as synaptic density are but static snapshots of a dynamic process in which both additive and regressive processes are continually in progress. Thus, there are probably not distinct and separate progressive and regressive phases, but a shift in balance between these processes during development. It is also worth noting that for any given cortical region there are often multiple waves of remodeling of synaptic architecture during development. Some of these waves of change in the morphology and density of synapses correspond to sensitive periods in which sensory or

environmental information can have maximum effect on the developing brain (Meredith *et al.*, 2012).

Oscillating rhythms

Even simple nervous systems show spontaneous activity that is only sometimes driven by sensory or motor events. Indeed, recent experiments in which stem cells were cultured *in vitro* to develop into neurons have observed that simple circuits can form with primitive oscillatory firing patterns (Shi *et al.*, 2012), suggesting that oscillatory activity is a fundamental property of nervous systems. In advanced brains, oscillatory activity can occur at multiple different frequencies simultaneously. These frequencies can vary from high (40 Hz or higher, generally characteristic of local circuit activity in cerebral cortex) to low (0.1 Hz or lower generally characteristic of longer range connectivity, or even glial cell activity). Oscillatory activity that is evoked by, or entrained to, sensory events can be studied with ERP or MEG methods (see Chapter 11). Many evoked potentials recorded at the scalp may reflect the entrainment of ongoing oscillatory activity at specific frequencies (Palva & Palva, 2012). In development, some of these spontaneous rhythms may have particular importance in consolidating or weakening structural and functional connections between regions.

From an early stage of prenatal development, interactions between cells are critical, including the transmission of electrical signals between neurons. In one example, patterns of

spontaneous firing of cells in the eyes (before they have opened and exposed themselves to light) transmit signals that appear to then help induce the layered structure of the lateral geniculate nucleus (see O'Leary & Nakagawa, 2002; Shatz, 2002). Thus, waves of firing neurons intrinsic to the developing organism may play an important role in specifying aspects of brain structure well before sensory inputs from the external world have any effect.

After birth, when the sensory systems are bombarded with stimulation, the spontaneous oscillations of the brain can become entrained or perturbed by sensory-evoked activity in ways that are still poorly understood (but see Palva & Palva, 2012). Oscillations at different frequencies are not just epiphenomena of patterns of neuron firing, but are likely to "bind" activity states across near and far regions of the brain. Indeed, some have argued that oscillation frequencies characterize distinct functional networks, and keep their information processing distinct from other concurrently active regions (Singer & Gray, 1995).

Scores of studies in developmental psychopathology have focused on differences in specific ERP waveforms assumed to reflect differences in regional patterns of activation, or the time course or degree of the latency jitter of these peaks of voltage change (e.g., Tye *et al.*, 2013). Common findings include less complexity to evoked waveforms and increased variability in their time course (Milne, 2011).

Resting activity and network connectivity

It has been hypothesized that resting state activity in the brain may provide a critical bridge between structural and functional development (Johnson, 2011). This is because resting states can reflect averages of sensory and task-driven activation patterns over a time period, and consolidation of experience-driven co-activation patterns between regions may require the prolonged activation patterns that resting or default states can provide. Specifically, regions that show coherent (in-phase) oscillatory activity may maintain or strengthen structural connections between them. Other regions that may oscillate at similar frequencies, but out of phase, may lose or reduce synaptic connections with the emerging coherent network.

Networks of resting state activity have been used to trace developmental changes in human brain networks and they even provided the basis for a "maturational index" (Schlaggar *et al.*, 2002). While several studies have shown a developmental shift from local to more long-range connectivity (e.g., Fair *et al.*, 2009), these studies are currently under question for methodological reasons associated with greater motion artifact at younger ages (Deen & Pelphrey, 2012). Another change in network structure during development is in the hierarchical structure. Adult networks have a more hierarchical structure that is optimally connected to support top-down relations between one part of the network and another (Supekar

et al., 2009). While hierarchical networks have a number of computational advantages, they are known to be less plastic and more vulnerable to damage or noise in the particular nodes at the top of the hierarchy. Thus, the network arrangement of children may be more adaptable in response to unusual or atypical sensory input or environmental context.

A final aspect of the transition from child brain network to the adult one is the greater connectivity between cortical and subcortical structures seen at younger ages (Supekar *et al.*, 2009), an observation that may be fundamental for our understanding of the emergence of the social brain and memory systems, as it implies that the specialization of some cortical areas may be initially more dominated by structures such as the amygdala and hippocampus.

Determinants of cortical specialization

A long-standing debate among those who study the developmental neurobiology of the cortex concerns the extent to which its structure and function in adults are the result of genetic, molecular and cellular level interactions, as opposed to being the result of the pattern of activity generated by firing of neurons. In the adult primate, most cortical areas can be determined by very detailed differences in their laminar structure, such as the precise thickness of certain layers. Often, however, the borderlines between areas are sometimes indistinct and controversial. It is commonly assumed that these anatomically defined areas have particular unique functions contained within their boundaries. While this has proved to be the case for early sensory and motor areas, there are many cases of *functional* regions that do not neatly correspond to known *neuroanatomical* divisions or borders.

Traditionally, two opposing possibilities have been put forward to account for the division of the cerebral cortex into distinct areas: *Protomap* and *protocortex*. According to the *protomap* (Rakic, 1988) view, differentiation into cortical regions occurs early in the formation of the cortex, and is due to intrinsic molecular factors. The alternative possibility is that different areas of cortex arise out of an undifferentiated *protocortex*. By this view, differentiation occurs later in the development of cortex, and it depends at least partly on extrinsic factors like input from other parts of the brain or sensory systems. The activity of neurons is required for regional differentiation (Killackey, 1990; O'Leary & Nakagawa, 2002). Reviews of the evidence converge on views that are midway between the *protomap* and *protocortex* hypotheses (Kingsbury & Finlay, 2001; Pallas, 2001; Ragsdale & Grove, 2001; Bystron *et al.*, 2008). Most agree that graded patterns of gene expression create large-scale regions with combinations of properties that may better suit certain computations (similar to a coarse or imprecise *protomap*). It is within these large-scale regions that smaller scale functional areas arise through the activity-dependent mechanisms associated with the *protocortex* view. Kingsbury and Finlay (2001) refer to this as a "hyperdimensional plaid"

because the patterning that emerges in a plaid is the result of small changes in many threads. Similarly, O’Leary and colleagues call this the “cooperative concentration” model since some different gradients of gene expression may act as opposing forces in shaping cortical regions (Hamasaki *et al.*, 2002).

Human functional brain development

Relating evidence on the neuroanatomical development of the brain to the remarkable changes in motor, perceptual and cognitive abilities during the first decade or so of human life presents a considerable challenge. To briefly recap on some of the earlier conclusions from this chapter, a probabilistic epigenesis view of development assumes interactions between genes, structural brain changes and psychological function are bidirectional, dynamic and emergent, as opposed to there being a unidirectional causal path from genes to structural changes to psychological consequences. We also saw that mammalian neurodevelopment is best characterized as being regulatory, rather than mosaic; the response properties of a cortical area is heavily interdependent upon its connectivity to other regions and their respective activity patterns. Further, with regard to structure-function mappings, the same overt behavioral responses can sometimes be supported by different combinations of regional activity within the brain, thus providing potential mechanisms for adaptation. We also saw how development can be viewed as a “restriction of fate,” and how plasticity becomes correspondingly reduced, as the fate of developmental process is restricted through the increase in specialization of cells or circuits.

Building on these foundations, the Interactive Specialization (IS) framework assumes that postnatal functional brain development, at least within the cerebral cortex, involves a process of organizing patterns of inter-regional interactions (Johnson, 2000; 2011), and it focuses on how partial or immature functioning of regions transitions gradually to their adult state. According to IS, the response properties of a given cortical region are partly determined by its patterns of connectivity to other regions, and their respective patterns of activity. During postnatal development, changes in the response properties of cortical regions occur as they interact and compete with each other to acquire their role in new computational abilities. From this perspective, some cortical regions start with poorly defined, general-purpose functions, and consequently are partially activated in a wide range of different stimuli, contexts and tasks. During development, activity-dependent interactions between regions sharpen up their functions such that their activity becomes restricted to a narrower set of circumstances (i.e., a region originally activated by a wide variety of visual objects may come to confine its response to upright human faces). The onset of new behavioral competencies will therefore be associated with changes in network activity over several regions, and not just by the onset of activity in one or more additional region(s).

Although the IS view can account for evidence from a variety of different domains of human cognition (Johnson, 2011), the area in which it has been most extensively tested is in face processing and in studies of the emergent specialization of the Fusiform Face Area (FFA). Several studies have traced the gradual emergence of a high degree of tuning to faces in this region. For example, Scherf *et al.* (2007) used naturalistic movies of faces, objects, buildings and navigation scenes in a passive viewing task with children (5–8 years), adolescents (11–14 years) and adults. They found that the children exhibited patterns of activation of the face processing areas similar to that commonly reported in adults (such as the FFA). However, this activation was not selective for the category of face stimuli; the regions were equally strongly activated by objects and landscapes.

While experiments such as these provide evidence for the increasing specialization (or tuning) of individual regions of the cortex during human postnatal development, it is clear from the IS viewpoint that the next step is to understand how *networks* involving different regions, each with their own different specializations, emerge. Again, face processing is a good test domain as a “core face network” of cortical regions has been well established in adults and activity in this network is modulated by task demands in adults. Cohen Kadosh *et al.* (2010) examined the emergence of the network underlying face processing in younger (7–8 year old) and older (10–11 years old) school-age children as well as young adults, and found that children showed substantially weaker connectivity within the face network. More notably, no evidence was found for the influence of task demands on the effective connectivity within the network in the two child groups. Thus, while both child groups exhibited similar overall network structures, these weaker networks were not influenced by top-down task demands.

Atypical human neurodevelopment

Consideration of two aspects of typical human brain development should inform our thinking about how things can go wrong to result in developmental psychopathologies. On the one hand, we have seen that constructing a typical brain requires an exquisite and complex series of interacting events in which there are many possibilities for specific events, or their timings, to go awry. From this perspective it is almost surprising how often a typical developmental outcome is achieved! On the other hand, we have also described a number of mechanisms of stability and inherent plasticity that constrain and guide the self-organization of the brain. Viewed from this perspective, brain development is an inevitable outcome of a combination of processes, and seems to be well buffered from any minor perturbations. From the latter perspective, one might speculate that in order to achieve significant deviation from the typical developmental trajectory either some fundamental process would have to be disrupted with likely widespread and devastating consequences, or multiple “minor” factors may have

to combine, which then prevent processes of adaptation and compensation from occurring.

Many of the key points from typical human neurodevelopment discussed earlier are of direct relevance to our interpretation of atypical developmental pathways. We have seen that development is a process of increased differentiation of cells, neural regions and networks. Although, for a particular environment, a specific trajectory of differentiation or specialization may characterize the majority outcome, we have also seen that apparently the same behaviors can be supported by different patterns of network activity at different ages. Even in the adult end-state, individual differences can be extensive, and recent research that compares groups of typical adult participants raised in different cultures has also shown a surprising degree of differences in the neural substrates of perceptual and cognitive functions (Chiao, 2009). Thus, the pathway of typical neurodevelopment should not be thought of as a single narrow track from which it is easy to deviate, but rather (to use Waddington's metaphor) as a deep and broad valley whose steep sides buffer against escape. Given that typical neurodevelopment is a broad and robust process, how are we to understand developmental psychopathologies?

Much of the neuroimaging work on developmental disorders such as autism and ADHD to date has aimed at identifying gross abnormalities in discrete brain regions, structures or systems. While there have been some specific claims made with regard to such deficits, reviews of the field tend to find instead that evidence is consistent with diffuse damage to widespread networks and regions of the brain (Deb & Thompson 1998; Rumsey & Ernst, 2000). In other words, we are seeing brains that have developed differently, rather than typically developed brains with overt or discrete damage.

This conclusion also extends to many developmental disorders of known genetic etiology such as Fragile-X, Williams Syndrome and Down Syndrome.

For example, Fragile-X involves the *FMR1* gene on the X chromosome. The defect of the gene results in a lack of the particular protein that it codes for: FMR1 protein. One of the knock-on consequences of the reduction of this protein is a disturbance in the neurotransmitter glutamate. However, despite the apparent specificity of this causal pathway, the effects of this defect are widespread and include several different aspects of physical and cognitive development. Thus, although Fragile-X involves only one gene, there are multiple and widespread neurodevelopmental consequences. Some of the broad effects may be the result of processes of adaptation at molecular, cellular and system levels.

Given these considerations, it is perhaps surprising that the vast majority of neuroimaging studies with developmental disordered groups involve participants from middle childhood to adulthood, and that patients are often grouped together over a wide age range (e.g., Kesler *et al.* (2004): Turner syndrome: 7–33 years; Pinter *et al.* (2001): Down's syndrome 5–23 years). For the IS approach, however, age of testing is critical, and

it is especially important to study infancy to understand partial causes of subsequent outcomes (Karmiloff-Smith, 1998; Paterson *et al.*, 1999). For this issue to be assessed, there need to be longitudinal imaging studies of clinical groups, or at least cross-sectional studies at different ages.

Risk

Traditionally, risk factors for human brain development were viewed as either intrinsic to the brain itself due to some pre- or perinatal neuroanatomical or neurochemical atypicality, or environmentally caused. More recently, it has become evident that at least for some of the more common developmental disorders, intrinsic and environmental factors may interact (see Chapter 10). Risk, as defined in the context of the robust, adaptive and self-organizing process of brain development, can be defined as the elimination of alternative options that are normally present.

As mentioned, in most developmental disorders we study brains that have developed differently. At the point of diagnosis, the relevant behavioral phenotypes are, by definition, clearly defined and well embedded. It is evident from the preceding discussion of developmental neurobiology that the phenotypic end state will include not only residual signs of the core atypicality but also compounded effects due to atypical intrinsic and environmental interactions and the results of adaptation. While the vast majority of neuroscience imaging work on children and adults with developmental disorders necessarily conflate these factors, Kaiser *et al.* (2010) used fMRI to study patterns of brain activation in children with autism, unaffected siblings of children with autism and controls while they viewed videos of biological motion. These authors found that unaffected siblings of children with autism had some patterns of activation in common with those with autism, but not controls. This "trait" activity was consistent with a "neuroendophenotype" that extends to unaffected family members, and raises the possibility that unaffected siblings actively overcome this atypicality in some way. Encouraging this view was the existence of patterns of activation consistent with "compensatory activity." These areas were not activated in either those with autism or the controls, and had the hallmark of regions whose additional activity allowed children potentially at-risk to achieve a typical outcome.

In considering the difficulty in interpreting neuroscience data from a brain that has undergone considerable postnatal adaptation, several groups have taken a new approach to developmental disorders based on the prospective longitudinal study of infants at-risk (most commonly, infant siblings in families with an older child already diagnosed). Here, the aim is to identify and study the earliest "pure" manifestations of the condition before the establishment of confounding and compensatory factors that result from the subsequent years of atypical development.

Resilience

Indirect evidence from studies of infants at-risk who may possess an endophenotype associated with a developmental disorder suggests that some of them additionally engage processes of neural adaptation or compensation in order to achieve a typical outcome. Given our review of the mechanisms of typical neurodevelopment, this should not be a surprise for several reasons. First, we have seen that the pathway for typical neurodevelopment can be broad and robust in the face of minor disturbances; a typical outcome is inevitable within certain boundaries. Second, we reviewed evidence that typical neurodevelopment is a constructive and autonomous process, which makes it inherently more robust and adaptable than the passive unfolding of a genetic “blueprint.” While the brain, viewed as a self-organizing autonomous system, is consistent with the ability to compensate in the face of adversity, can we specify in more detail the neural systems, regions or mechanisms that may underlie this process?

The unique developmental history of the anterior portion of cortex—PFC—results in the beginnings of activity-dependent development of neural connectivity in the absence of thalamic input, and this may bias the region toward processing information based on intercortical connectivity rather than the close connections to sensory input or motor output characteristic of more posterior regions. It is notable that several common developmental disorders have been associated with deficits in the so-called executive functions (EF) that are generally thought to be supported by PFC (see Chapter 10). While EF deficits often co-occur with diagnostic symptoms in these disorders, evidence indicates that they are, to at least some extent, dissociable (Johnson, 2012). One hypothesis is that instead of poor EF skills being part of a core cluster of symptoms of atypicality or impairment in some developmental disorders, having good EF skills allow the brain to compensate, or better adapt to, atypical functioning in other neural systems in individuals at genetic risk (Johnson, 2012). By this view, poor executive function and self-control skills are associated with some developmental disorders as some of the individual children who end up with these diagnoses have less capacity to compensate in the face of other risk factors early in life. In contrast, individual children with strong EF skills have brains that are better able to adapt at a neural systems level, and thus are less likely to end up with a diagnosis. On the other hand, being at the lower end of typical variation in EF skills early in life may be considered to be an additional risk factor, due to less capacity to adapt in response to other perturbations to the typical developmental pathway.

The traditional view of PFC atypicality in developmental disorders is that later developing regions of the brain are more vulnerable to perturbation at earlier stages. However, recent evidence indicates that the PFC is actively involved in the acquisition of new skills and knowledge from very early in life, and, additionally, that it may play a significant role in establishing and organizing functional specialization in posterior regions of

the cortex (see Johnson 2011, for a review). On the assumption that PFC can support at least some EF skills from early in life, and that it plays a role in shaping and organizing other cortical networks, it is reasonable to infer that it may have a critical role in the adaptive reorganization of other cortical pathways in the face of nonoptimal functioning elsewhere.

As discussed, some MRI studies are beginning to reveal glimpses of the processes of brain adaptation that may result in typical outcomes from some children born at-risk, and the compensatory mechanisms that often involve parts of PFC. For example, in Kaiser *et al.* (2010) the compensatory activity regions were right posterior STS (consistent with biological motion processing) and ventromedial PFC. While the adult functions of the latter region remain unclear, it is often assumed to have a role in the regulation of other brain systems and decision-making (Bechara *et al.*, 2000).

Future directions

Developmental neurobiology is an exciting and very rapidly moving field, with new techniques and methods becoming available every few years. However, the allure of obtaining new kinds and quantities of empirical data should not distract us from the key questions and issues around human developmental psychopathology. It seems likely that for many developmental disorders we will need to understand how large-scale networks of neurons are influenced by alterations of their underlying molecular and cellular function. It will be important to remember that different molecular or cellular atypicalities can sometimes give rise to the same functional consequences at an overall neuronal network level. Thus, ultimately it may be at the level of whole neural systems that some developmental disorders are best understood. However, this change in focus requires us to have a better understanding of the temporal and spatial dynamics of multicellular activity in the brain, something that has been hampered by the fact that most current neuroimaging methods have either relatively poor spatial or temporal resolution.

We began this chapter by stating that the brain is primarily an organ of adaptation at multiple different temporal scales and levels of organization. An exciting challenge for the future will be to understand these processes better and ultimately to harness them in ways that may allow us to reduce the number and/or severity of symptoms of children who end up with diagnoses such as autism and ADHD.

Definitions

Differentiation—the process through which cells take on their final (adult) morphology

Endophenotype—an intermediate phenotype often associated with neural processes or systems

Epigenesis—the expression of genes during development
 Laminar—refers to the layered structure of cerebral cortex
 Migration—the travelling of cells from their location of origin
 Myelination—the process of depositing a fatty sheath around neural fibers
 Neurogenesis—the process of generating new neurons
 Progenitor cells—stem cells that give rise to neurons

CHAPTER 10

Systems neuroscience

Daniel S. Pine

Section on Development and Affective Neuroscience, National Institute of Mental Health (NIMH) Intramural Research Program, Bethesda, MD, USA

Introduction

The term “systems neuroscience” refers to research on neural circuits, which represent collections of neurons that coalesce to function as a unit. Systems neuroscience applications in child psychology and psychiatry examine how brain circuits influence behavior, as it changes in typical and atypical development, often assessed through brain imaging.

These applications are only beginning, unfolding at the interface of psychology, psychiatry, information technology, genetics, and other fields. Newly emerging, multidisciplinary fields often undergo considerable changes with time, complicating attempts to define their boundaries. So it is with systems neuroscience. While interesting applications utilize brain imaging, this is not a prerequisite; relevant research also can focus only on behavior, studied where supporting neural systems have been delineated. Similarly, relevant research can link behaviors to genetic factors by again focusing on behaviors tightly linked to underlying neural systems. In such examples, research in children usually extends mechanistic understandings established through research using methods too invasive for applications with children.

Since specific examples illustrates applications, the bulk of this chapter focuses on four examples: cognitive control, fear, attachment-affiliation, and brain development. Given the multidisciplinary nature of these examples, this chapter overlaps with other chapters but has a uniquely integrative focus to illustrate insights that emerge at the interface of allied disciplines. Figure 10.1 charts how an integrative lens can be applied either narrowly or broadly.

Figure 10.1 depicts the multitiered nature of the targeted phenomena, uniting around the shared pursuit of mechanistic understandings of brain–behavior relationships. At its most focused level, depicted in the top row of Figure 10.1, research

targets the genome and its effect on function in individual neurons, extending to brain systems that coalesce through connections among a few such individual neurons to form a circuit. This level can be slightly expanded to examine interactions among components of brain circuits and their effects on behavior, as depicted in Figure 10.1 in the transition from the top to the middle row. Of note, evolutionary perspectives on these inquiries even more broadly inform understandings, as discussed in the chapters on genetics. For example, humans’ evolutionary divergence from other primates may reflect cross-species differences in genetic regulatory elements related to cross-species differences in behavior and associated brain functions. Advances in neuroscience also inform genetic research, as reflected in the use of pathway analysis in genetics, informed by neuroscience.

Neuroscience advances provide unique opportunities. Great excitement has emerged for optogenetics, which has become a classic tool (Deisseroth, 2012). With this technique, most typically applied to rodents, activity in neural circuits can be precisely manipulated with great spatial and temporal precision so that the corresponding changes in behavior can be charted. At a more macroscopic level, applications to children often use imaging to chart the connections between behaviors expressed in the laboratory and variations in brain function. Figure 10.1 depicts these levels from the middle to the bottom row of the figure. Still more macroscopic applications can focus on these same sets of behaviors, expressed in the laboratory, as they relate to clinical profiles, expressed through thoughts and behaviors in children’s daily lives, as depicted in the bottom row of Figure 10.1. This aspect of the figure also shows how features in the environment, depicted in the classroom, also impact on each level shown in the figure. Finally, by linking so many levels, systems neuroscience becomes clinically relevant.

Figure 10.1 Relationships among constructs targeted in systems neuroscience. The upper left-hand corner depicts molecular-genetic targets in DNA, as they relate to neuron function, depicted toward the right. Individual neuron function can be related to the functions of neural circuits, composed of collections of neurons. This also is depicted in the figure. Finally, these neural circuits can be studied through imaging, in structures that can be assessed in children using brain imaging. With this technique, the functions of the circuit in the child can be related to the functions that children display in their world, as depicted by a frightened child attending school. Finally, it is emphasized how the environment interacts with each level of this multitiered system, extending from the classroom through the molecular-genetic targets displayed in the upper left-hand corner of the figure.

Child psychiatry and systems neuroscience

Understanding systems neuroscience requires mastery of material handled in allied disciplines, particularly material reviewed in the chapters on brain imaging, experimental models, and developmental processes. Readers are encouraged to review these chapters, while referring to Figure 10.1 and searching for mechanistic explanation of specific behaviors as outputs from neural circuits.

Molecular genetics examines the many ways in which deoxyribonucleic acid (DNA) influences neural-circuit function and behavior (Pine *et al.*, 2010). Research in this area links DNA variation to variation in behavior either occurring directly or through interactions with the environment. Chapters in Part II (Influences on Psychopathology) describe core features of the genome that influence behavior. Other sections also relate to systems neuroscience. Because brain imaging research assesses structural and functional variation in neural circuits, this material, appearing in Part I of the textbook, vitally informs

child psychiatry and psychology applications of systems neuroscience. Summaries in these chapters describe key principles emerging from research using methods too invasive for applications to children. Across all of these areas, emphasis is placed on how genes interact with factors in the environment, as is also represented in Figure 10.1.

Chapter 11 provides in-depth descriptions of various techniques, whereas the chapter on development (see Chapter 9) focuses on age variation in brain–behavior relationships. Only small portions of the vast research on imaging, animal models, or developmental psychopathology deeply probe connections between brain systems and specific behaviors with the goal of answering clinically relevant questions. Such a deep probing is the backbone of this chapter, provided through a focus on four specific examples.

While the four examples target distinct areas, they share three features. First, each begins by targeting specific behaviors, ideally ones that can be studied through observation in the laboratory to support cross-species research essential for progress in systems neuroscience. Second, a foundation is laid for expansive research, broadening the field in two opposite directions; one direction focuses on complex behaviors that children display in the world. The second proceeds in the opposite direction, to increasingly narrow contexts. The third and final feature is that for each example, clinically relevant questions are proposed, where answers have not emerged without the tools of systems neuroscience. For illustrative purposes, each example emphasizes one unique contribution, although each example could address many questions.

Finally, emerging systems neuroscience research fails to find clear associations between measures of brain function and psychiatric syndromes as they are currently conceptualized. This may reflect heterogeneity, where children classified as suffering from the same syndrome actually exhibit syndromes that result from distinct pathophysiology. This also may reflect the occurrence of unique clinical profiles from one core form of brain dysfunction, as described in Chapter 24. Given the current state of systems neuroscience research, clinicians can expect the boundaries of mental syndromes to change, much as they do for neoplastic diseases as pathophysiology of cancer is understood in increasing detail.

Cognitive control

Defining specific behaviors

Research on cognitive control usually examines how neural-circuitry function varies during motor-response tasks. In these situations, cognitive control supports two processes: error monitoring and behavioral adjustment (Cohen *et al.*, 2004; Carter, 2005; Carter, 2006; van Veen *et al.*, 2008).

Many tasks engage cognitive-control processes. These include tasks of so-called executive functions, selective attention, delayed motor response, and response reversal. For illustrative

Figure 10.2 Research on cognitive control. (a) The flanker task is displayed on a screen and the corresponding depiction of a child viewing the screen represents brain regions that are engaged when this task is performed in a brain scanner. (b) The error-related negativity (ERN) response, which is recorded from a child's scalp using electroencephalography. (c) Data collected from neurons of a monkey performing a reward task shown in the figure. Over time, individual events with or without a stimulus presented elicit responses that can be plotted in a so-called "raster" diagram. This is shown immediately adjacent to the monkey. These yield characteristic responses in different parts of the cognitive control circuit to instructions, triggers, and food cues, as also is shown in (c).

purposes, Figure 10.2a depicts the format for one such task, the flanker task, which has been used extensively (Nigg, 2007; Geburek *et al.*, 2013). As shown in Figure 10.2a, subjects typically choose one of two responses that are signaled by task stimuli, such as a right-hand or left-hand button press, as indicated by rightward- or leftward-pointing arrows in Figure 10.2a. Difficulty can be adjusted on this task by changing the appearance of arrow targets. For example, on some task trials, target features can be degraded, by making the arrow appear blurry, or a target stimulus can be surrounded by distracters, such as a rightward-pointing target arrow appearing amidst a number of other leftward-pointing arrows. Figure 10.2a presents such a stimulus pattern, with a degraded rightward arrow surrounded by five darker leftward-pointing arrows.

Neural circuit responding has been precisely charted for two specific behaviors that occur on the flanker and similar tasks. One represents the correct execution of a difficult response, such as pushing a right-hand button to a rightward-pointing blurry target arrow in Figure 10.2a that appears among multiple, clear and bright leftward-pointing distracter arrows. Such difficult responses are said to require engagement of cognitive control to minimize probability of errant responding. Another such behavior represents the response to an error, such as a left-hand button response to the trial in Figure 10.2a mentioned earlier,

necessitating a right-hand response. Here, cognitive control initiates a series of behavioral adjustments. In both instances, such behaviors represent the typical targets of systems neuroscience research that maps changes in components of neural circuits that unfold during these events.

Linking the behavior to clinical questions

Systems neuroscience research begins to become clinically relevant when it links precisely delineated behaviors, observed in the laboratory, to clinically relevant behaviors, observed in the world. For cognitive control, research on attention deficit hyperactivity disorder (ADHD) and obsessive compulsive disorder (OCD) demonstrates potential clinical relevance. Both disorders exhibit signs of perturbed cognitive control, as do many other mental illnesses (Carter & Barch, 2007; Hajcak *et al.*, 2008; Geburek *et al.*, 2013), potentially arising from shared involvement of cognitive control deficits (Marsh *et al.*, 2009). Interest on cognitive control research in ADHD and OCD follows from the observation that these two highly comorbid syndromes (Peterson *et al.*, 2001) manifest discrepant signs of cognitive-control perturbations. Thus, ADHD involves reduced cognitive control (Nigg, 2007; Geburek *et al.*, 2013), whereas OCD involves the opposite (Hajcak *et al.*, 2008). Additional information concerning these disorders can be found in Chapters 55 and 61.

Examining the neural circuitry supporting the behavior

While many tasks have been linked to pediatric mental illness, research on cognitive control delineates the underlying neural architecture with particular clarity. Much of this work relies on brain imaging studies in adults and invasive studies in nonhuman primates to show that cognitive control is mediated by a neural circuit connecting four principal structures: the medial prefrontal cortex (mPFC) encompassing the anterior cingulate gyrus, the dorsolateral PFC (DLPFC), the basal ganglia, and the dopaminergic neurons of the ventral tegmental area (VTA) (Schultz, 2001; Cohen *et al.*, 2004; Corbetta *et al.*, 2008). Figure 10.2a also illustrates the architecture of this circuit, where the DLPFC, basal ganglia, and anterior cingulate all are labeled. Moreover, the rudimentary functions of these individual components also have been delineated, though some controversy remains concerning the precise details. The DLPFC is thought to represent stimulus-action rules (Miller & Cohen, 2001), modulating activity throughout the circuit based on these representations, whereas the VTA is thought to generate a prediction error signal, which can train this circuit over time, interacting with the mPFC and the basal ganglia (Schultz, 2001).

Figure 10.2c depicts relevant research. Work on VTA function in monkeys is particularly elegant, where the VTA has been shown to respond to errors in a way that suggests representation of error signaling. Work in rodents extends these studies by further implicating the dopaminergic system in error signaling. Taken together, studies in rodents and nonhuman primates

delineate effects on cognitive control with increasing depth and precision, proceeding to the molecular level. For example, the effects of genetic manipulations have been examined (Barnes *et al.*, 2011), which has allowed research in humans to link variations in dopamine genes to variations in brain function and behavior.

Through imaging and electrophysiology, research maps neural correlates of cognitive control perturbations in ADHD and OCD. In both disorders, signs of dysfunction have been detected in mPFC, DLPFC, and the basal ganglia (Hajcak *et al.*, 2008; Cortese *et al.*, 2012; de Wit *et al.*, 2012; Geburek *et al.*, 2013), which are thought also to involve dopaminergic deficits (Barnes *et al.*, 2011). For this chapter, the most relevant findings map differences between ADHD and OCD. In ADHD, the findings suggest a degraded representation of error signals. This is illustrated in research on error-related negativity (ERN), as is also illustrated in Figure 10.2 and appearing in panel 2b. ERN reflects the rapid propagation of a brain signal that occurs in the earliest stage of error commission, before an individual has awareness of the error. This is thought to arise from VTA-to-mPFC signaling (Cohen *et al.*, 2004). In ADHD, reduced error representation manifests for the ERN. In OCD, the opposite manifests, with signs of enhanced ERN.

Extending the current literature

Clearly, this work differentiating ADHD and OCD represents progress, but even greater potential exists for future advances. In this chapter, the four examples illustrate four possible future advances. While each example offers promise for addressing many questions, for illustrative purposes, one specific promising avenue is discussed in each example.

Research on cognitive control shows particular promise in addressing questions on the origins of comorbidity. How can we understand such comorbidity? Despite apparent clinical dissimilarity, does observed comorbidity actually reflect mislabeling of one core, underlying syndrome as two distinct entities? Alternatively, does comorbidity arise from distinct complications of a shared risk factor that ultimately produces over time two distinct syndromes? Finally, is the relationship between the two phenotypes an epiphenomenon, arising due to a superficial resemblance of two syndromes that in reality share very little? These are questions for which systems neuroscience ultimately might provide answers.

In the knowledge of brain-behavior relationships, techniques may advance to the point where neural measures can precisely quantify cognitive control functions in children, using the next generation of measure similar to the ERN. As invasive studies in animals continue to elucidate the causal relationships between brain function and behavior, this knowledge will inform understandings of brain-behavior relationships in children, as quantified with this next generation of measures. The unique patterns currently observed in ADHD and OCD may be increasingly understood, to the point where they will be shown to represent distinct malfunctions. Such a demonstration

will require longitudinal research that charts in tandem changes in brain function and clinical expression.

This could generate findings that resemble those in work on the molecular architecture of cancer, where clinically similar scenarios reflect distinct pathophysiology. Here, distinct types of cancer are identified on the basis of core features of underlying organ system function and genetics. On the other hand, the next generation of cognitive control measures may reveal the unique patterns in ADHD and OCD to reflect strongly shared features, to the point where the two disorders represent alternative manifestations of one process. In this case, distinct late-stage disturbances in the underlying neural architectures would give rise to unique clinical presentation. As brain imaging and electrophysiologic measures advance, these alternative possibilities one day will be adjudicated, allowing clinicians to further subclassify clinical presentations with measures that precisely map pathophysiology.

Fear

Defining specific behaviors

Research on fear shares many features with research on cognitive control. Thus, in both areas, cross-species research maps the underlying neural architecture of specific behaviors that have been conserved across evolution. Perhaps more strongly than in many other areas, this is demonstrated by the remarkable cross-species conservation of brain-behavior relationships as they manifest in fear-related behavior (LeDoux, 2000; Phelps & LeDoux, 2005). Such conservation allows translation of conclusions in one species to another. Moreover, both research on cognitive control and fear target relatively narrow behaviors. However, in other respects, the nature of these behaviors is quite different. Research on cognitive control typically uses difficult motor tasks, whereas applications in research on fear typically expose children to mildly threatening stimuli, such as loud sounds or pictures of angry faces. Some of the most promising research then has mapped responses in two neural circuits, as reflected in two sets of behaviors, illustrated in Figure 10.3.

One set uses fear conditioning, where a neutral conditioned stimulus (CS+) is paired with an aversive unconditioned stimulus (UCS), as depicted in Figure 10.3a, in rodents on the left and humans on the right. In this scenario, children acquire fear of the CS+, as indexed by self-report, behavior, and physiology (Pine *et al.*, 2009). Such fear also can be extinguished by repeatedly presenting the CS+ after conditioning in the absence of the UCS (Quirk & Mueller 2008). The responses expressed by children on these tasks resemble those exhibited by adults and by various other organisms, exposed to comparable procedures. These experiments quantify aspects of learning, where systems neuroscience deeply maps the relevant circuitry.

The second set examines how aversive stimuli capture attention, as illustrated in Figure 10.3b. Because the primate brain is “capacity limited,” attention facilitates appropriate evaluation

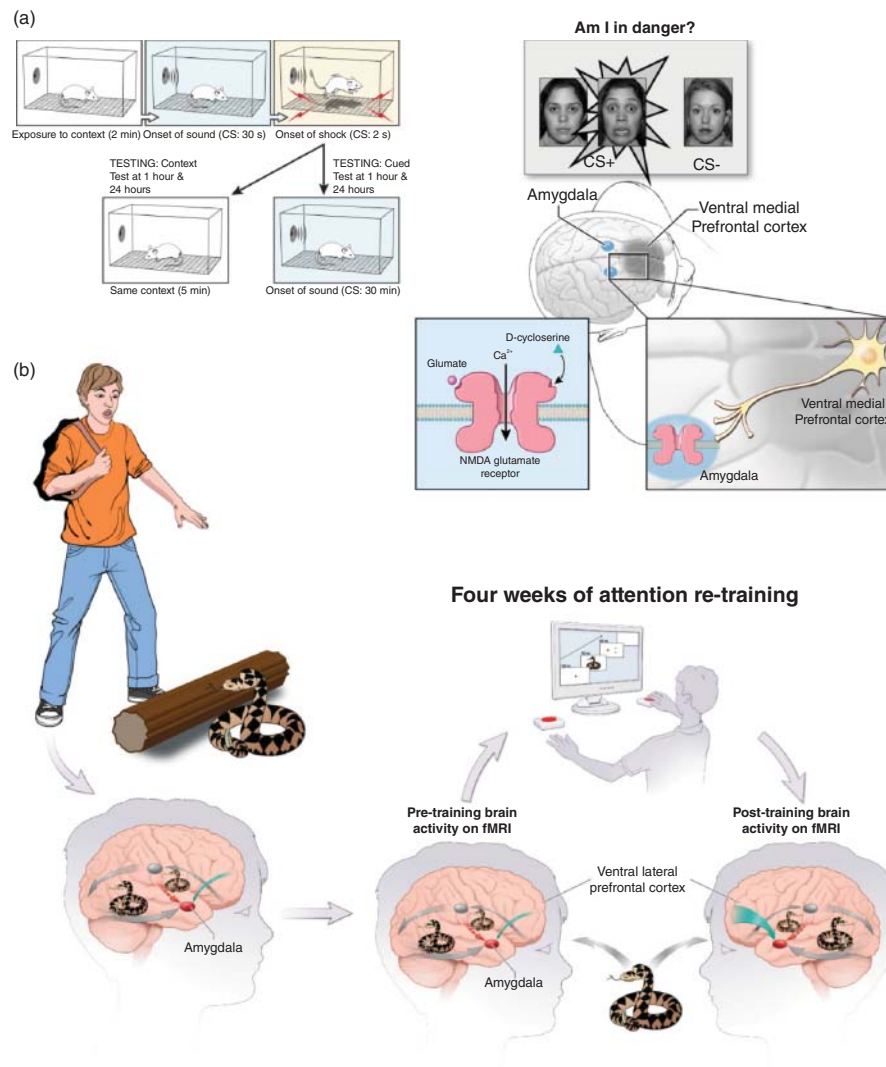

Figure 10.3 Two aspects of research on anxiety that inform therapeutics. (a) Work on conditioning and extinction, with the left half of the figure showing a fear conditioning experiment in rodents and the right half showing circuitry that is thought to be engaged in humans, during extinction. This shows the specific connection between the prefrontal cortex and the amygdala. This includes a depiction of the location where D-cycloserine stimulates the NMDA receptor, which may facilitate extinction and clinical response to cognitive behavioral therapy. (b) Work on attention orienting, as occurs when a threat, such as a snake under a log, is encountered. The circuitry engaged during attention orienting also is shown, as is an apparatus that might be used to provide attention retraining and induce changes in this circuitry.

of the environment by appropriately allocating the brain's limited neural resources (Corbetta *et al.*, 2008). Aversive stimuli receive priority for processing, eliciting attention orienting (LeDoux, 2000; Bar-Haim *et al.*, 2007). This attention response can be quantified using many tasks; one of the most frequently employed procedure uses the “dot-probe” task to present children with two stimuli, before quantifying attention allocation based on eye movements or reaction times. As with conditioning, the relevant circuitry has been mapped with great precision (Pine *et al.*, 2009).

For both areas, many findings extend research in basic science to the clinic by using measures of peripheral physiology, as reviewed in separate chapters on disorder-specific

pathophysiology. For example, considerable research implicates perturbed hypothalamic-pituitary-adrenal (HPA) axis function in both depressive and trauma-related disorders, as reviewed in the chapters on these conditions. Similarly, other research examines relationships between anxiety and measures of autonomic function, as can be captured through assessments of heart rate or skin conductance. Such research emphasizes the need to consider relationships that both brain and mind show with these and other measures of bodily function, as they typically are quantified through measures of peripheral physiology.

Nevertheless, recent systems neuroscience research on psychopathology more frequently relies on brain imaging measures as opposed to such HPA-axis-related or autonomic

measures. This is because the most frequently used HPA axis and autonomic physiology measures exhibit relatively weak and inconsistent associations with measures of psychopathology. Some suggest that this reflects the fact that peripheral measures of physiology are influenced by many factors outside of central nervous system function, though work does continue to advance the field using peripheral markers in some areas (Staufenbiel *et al.*, 2013). These suggestions in turn generate interest in acquiring more direct measures of central nervous system function through brain imaging, with the hope of demonstrating stronger relationships between clinical profiles and biological indices.

Behavior, clinical questions, and neural circuitry

Considerable research has studied fear conditioning and extinction in healthy and anxious individuals, as summarized in meta-analysis (Lissek *et al.*, 2005). The ability to acquire fear actually appears similar in children, adolescents, and adults with or without anxiety disorders. The neural architecture of this ability also has been precisely delineated, both in rodents and primates (LeDoux, 2000; Phelps, 2006). This requires changes in a neural circuit encompassing the amygdala, a medial temporal lobe collection of nuclei. Imaging studies also implicate the amygdala in conditioning among children, much as they have done in adults (Lau *et al.*, 2011). While no imaging studies have compared amygdala function in anxious and healthy children during conditioning, one would expect intact amygdala function on conditioning tasks in anxious children, based on data from other conditioning studies. This contrasts with work on amygdala response to innate dangers, where anxious children show enhanced responses relative to healthy children (Beesdo *et al.*, 2009; Pine *et al.*, 2009). Such findings demonstrate the context specificity of amygdala dysfunction in pediatric mental disorders. This dysfunction only manifests in particular contexts, complicating attempts to chart brain-behavior associations.

Conditioning is probably intact in most anxiety disorder patients, but anxious and healthy individuals do have a number of difficulties in other aspects of fear learning. Specifically, anxious individuals more consistently differ from nonanxious individuals in their ability to rapidly learn to make subtle distinction when classifying the boundaries that separate various, similar-appearing threat-related and safe stimuli (Britton *et al.*, 2011). Such distinctions must be made in extinction tasks, where a previously conditioned CS+ stimulus is repeatedly presented in the absence of the UCS, which leads a subject to reclassify the previously dangerous CS+ as an ambiguous threat, one that used to be dangerous but is now safe. This requires a more subtle form of learning than occurs during conditioning, and such learning engages a neural circuit that connects the medial PFC (mPFC) to the basolateral nucleus of the amygdala (Quirk & Mueller, 2008); there is some evidence of perturbed extinction and perturbed mPFC-to-amygdala circuitry dysfunction in anxiety disorders (Greenberg *et al.*, 2013).

While considerable work examines conditioning, an even broader series examines attention orienting (Bar-Haim *et al.*, 2007). In fact, differences in orienting probably represent the most consistent information-processing finding in anxiety. Patients with anxiety disorders consistently show a tendency to orient more strongly to threats than healthy individuals, and this tendency manifests tremendously quickly, even to threats that are presented so rapidly that their occurrence cannot be reported by the patient. Such attention biases have been shown to reflect dysfunction in the same underlying neural circuit that supports attention orienting in the primate (Pine *et al.*, 2009). This circuit connects the amygdala, which is engaged immediately by threat presentation, to the insula and ventrolateral expanse of the PFC, which is engaged more slowly to support attention deployment after threat detection.

Extending the current literature

Research on cognitive control illustrates how systems neuroscience principles inform comorbidity. Research on fear informs therapeutics.

Research on extinction charts the relevant underlying molecular architecture, as depicted in Figure 10.1. This work shows that various chemical manipulations can enhance a rodent's ability to learn the boundaries that separate threat and safety signals. From the clinical perspective, interest has focused on one particular compound, d-cycloserine (DCS), which is an antibiotic that also has effects on the glycine-sensitive site on the N-methyl-D-aspartate (NMDA) glutamate receptor. If patients with anxiety disorders have deficient capacity to learn threat-safety boundaries, this deficit may reflect deficient functioning of the mPFC-amygdala circuit, which relies on the NMDA receptor to facilitate communication in the circuit to support extinction learning. Moreover, if DCS increases functioning in this circuit, specifically at times when threat-safety boundaries are being learned, DCS administered briefly, during exposure therapy sessions that occur in cognitive behavioral therapy (CBT), might enhance the patient's response to CBT. This idea is presented pictorially in Figure 10.3a. Thus, this figure shows the connections between the human amygdala and ventromedial prefrontal cortex that would be engaged by an extinguished CS+, in the form of a picture of a woman. This figure also shows the microscopic connection between a neuron in this frontal region, which synapses in the amygdala, where an NMDA receptor is depicted, with a binding site for DCS. Of note, other work has pursued different approaches, using knowledge about fear extinction to derive other pharmacological approaches or even nonpharmacological means for diminishing fear through effects on underlying brain circuitry (Pine *et al.*, 2009; Schiller *et al.*, 2010; Agren *et al.*, 2012). While these other approaches have been studied in less depth than approaches relying on DCS, the overall series of research in humans produces novel ideas about treatment for pediatric anxiety disorders.

Findings from randomized controlled trials in both pediatric and adult anxiety disorders provide some preliminary support for the idea that DCS exerts beneficial clinical effects in patients undergoing CBT (Ressler *et al.*, 2004; Storch *et al.*, 2010). That is, in at least a few trials, patients randomized to CBT with DCS show more robust responses than patients randomized to CBT with placebo. Nevertheless, findings are far from clear. As a result, it will be many years before DCS or any similar form of treatment can be recommended for routine clinical use. Regardless, the mode of thinking that led to research on DCS provides an avenue for many other treatments. Such treatments emerge not from the serendipitous clinical observations that have produced most treatments for mental disorders but rather from an understanding of pathophysiology.

In a similar fashion, research on attention orienting also generates novel ideas for new therapies. These ideas extend observations on the underlying neural circuitry that sustains threat-related attention biases in pediatric anxiety disorders. Such biases are thought to reflect perturbed function in a circuit connecting the amygdala to the insula and adjacent ventrolateral PFC. Again, this idea also is presented pictorially in Figure 10.3, specifically in the lower part of the figure as Figure 10.3b. Thus, while extinction involves amygdala-medial-PFC connections shown in Figure 10.3a, attention involves amygdala-lateral-PFC connections shown in Figure 10.3b, demonstrating the key principles of systems neuroscience that link specific behaviors to particular brain circuits (Pine *et al.* 2009). For biases in attention, this perturbed function is considered to be “implicit,” because it is expressed very rapidly, so rapidly that patients cannot describe the nature of their attention dysfunction to a therapist; perturbed function even manifests to threats that are presented too rapidly to be reported. In Figure 10.3b, natural threats, such as snakes or angry faces of peers, are thought to very rapidly engage amygdala-based circuitry, more rapidly than in circuitry in the ventral part of the cerebral cortex. This creates the implicit bias in threat-attention interactions. Neuroscience research shows that such implicit biases can be changed more easily and strongly through repeated training than through declarative instruction. Thus, CBT targets biases in attention by instructing patients on the nature of their underlying biases in attention toward threats. Such attempts to change attention in anxious children may be augmented through implicit training procedures that address the underlying rapidly deployed perturbations in brain circuitry.

Attention bias modification training (ABMT) represents an attempt to provide such implicit training of attention. This treatment targets rapidly deployed implicit perturbations through repeated, computer-based training. ABMT can use various procedures, but the most common application repeatedly exposes children to the same types of stimuli used in the dot-probe task, where threat and neutral stimuli are presented side by side. However, in active ABMT, probes repeatedly appear behind the neutral stimulus, which implicitly teaches children to automatically and reflexively avert their attention

for threats. Considerable research uses this technique to reduce threat biases in adult and pediatric anxiety disorders, where preliminary evidence of efficacy has emerged (Hakamata *et al.*, 2010; Eldar *et al.*, 2012). Other work uses alternative ABMT procedures that teach children to attend toward positive stimuli, extending other work linking an avoidance of positive stimuli to anxiety (Waters *et al.*, 2013). Much as in work on extinction and DCS, the major insight to emerge from research on ABMT and threat-related attention bias relates to the process of scientific discovery. The field still remains many years removed from a standard ABMT-like treatment that can be widely applied. However, the process of discovery illustrates a path for future treatment discovery. This path involves the delineation of an underlying behavioral correlate and its neural underpinnings, which then provides knowledge on the most appropriate means for altering the behavior.

Attachment and affiliation

Defining specific behaviors

The third example, attachment and affiliation, considers the neural underpinnings of other specific behaviors that can be isolated and quantified in the laboratory. Work in this area is relatively unique, when contrasted with research on cognitive control or fear. For these first two constructs, the behaviors elicited in humans resemble quite closely the behaviors elicited in rodents and nonhuman primates (see Chapter 6). In fact, many of the paradigms readily translate across species. However, for attachment and affiliation, the differences in rodents, nonhuman primates, and humans force the relevant systems neuroscience research to adopt unique methods in each species. This illustrates a key puzzle that must be solved in all cross-species systems neuroscience research: questions must be addressed in each species at an appropriate level of abstraction, so that species-typical behaviors can be studied in a form that is still applicable to other species. This puzzle has proved relatively easy to solve in work on cognitive control and fear but has been more difficult in research on attachment, given cross-species diversity in attachment and other social behaviors.

Fundamental research on attachment and affiliation probes the behaviors from mothers and their infants that serve to maintain the bond between the two individuals (Carter, 1998). This includes a set of studies targeting behaviors exhibited by the mother and by the offspring that support maintenance of a social bond. Work that appears particularly clinically relevant targets the ways in which mothers and infants respond to particular cues that each partner of the dyad presents to the other. For example, considerable work examines the degree to which the sight, smell, and sound of the infant elicits specific behaviors from the mother, many of which serve to maintain attention orientation and approach behaviors, keeping the infant in close contact with the mother. Similarly, other work examines the unique response elicited in the infant from cues associated with

the mother, sometimes presented to the infant within hours of birth. Both sets of studies demonstrate the priority that infant and mother cues receive, when they are presented to each pair of the dyad, amidst a collection of other cues. Recent interest specifically explores the ways in which primate infants respond to their mothers with imitative behaviors, initial signs of emerging processes that might ground future social development (Paukner *et al.*, 2011).

Insights for human attachment behaviors have emerged from cross-species research. This work shows tremendous diversity in the way in which mothers and infants respond to each other, in terms of the specific behaviors and the timing of their expression. Particularly important work compares behaviors among species of voles, rodents common throughout the United States, which generally exhibit great cross-species similarity in physiology and behavior (Insel *et al.* 1993; Carter, 1998). However, two distinct species of vole exhibit markedly different patterns of attachment behavior, emerging against a background of otherwise great similarity in behavior and physiology. In one species, the prairie vole, attachment occurs in a context of rich social behavior among adult male and female voles, which typically are highly social. This pattern contrasts with expression of attachment in the montane vole, where attachment represents an aberration, involving a time when infant voles are raised by their mothers, who typically experience a relatively isolated social existence, including minimal contact with males. Figure 10.4a illustrates these two rodent species, represented as the solitary-appearing montane vole and the social prairie vole. These precise differences in rodent behavior have been used to stimulate other work that has gone on to delineate the underlying neural architecture of attachment in nonhuman primates and humans. This too is illustrated in the distribution of oxytocin receptors in these two species of voles, as is also illustrated in Figure 10.4a. Changes in levels of oxytocin influence breastfeeding and other aspects of maternal behavior. As a result, research linking attachment to central nervous system distributions of this chemical is consistent with the known relationship between oxytocin and maternal behavior. While research on oxytocin focuses most closely on attachment behaviors, this chemical is also relevant to fear-related behaviors described in other sections of this chapter. This may reflect the fact that oxytocin-releasing cells in the brain are in direct contact with hypothalamic neurons that release important regulators of the HPA axis (Feldman, 2012).

Linking the behavior to clinical questions

Like cognitive control, perturbed attachment behavior has been linked to an array of developmental psychopathologies. In fact, a class of mental disorders has been labeled as “attachment disorders” based on the clinical disruption in the parent–child bond. As with the research on cognitive control and fear, studies of attachment behavior conform to a systems neuroscience approach when they adopt a particular approach. This approach must be grounded in precise understandings of brain–behavior

associations, as reflected in functions of dedicated, precisely defined neural circuits. In clinically focused work in child psychiatry and psychology, research on autism spectrum disorders (ASDs) provides one compelling application of systems neuroscience research on attachment. ASDs are recognized as prototypical developmental disorders, which manifest as perturbed maturation of social behavior (see Chapter 51).

A range of paradigms have been used to quantify the social deficits of children with ASDs, with a particularly large number of studies quantifying the responses to faces (Cicchetti *et al.*, 2011). A particularly compelling line of work focuses on attention allocation (Kaiser *et al.*, 2010). Since ASDs are thought to arise within the first year of life, great interest has focused on extending research on social processing to the earliest phases of social development. Here, the best understood process is attachment and affiliation, generating great interest in charting the evolution of attachment behavior in ASDs. Clearly, precise quantification of attachment behaviors in humans is difficult, particularly using the most sophisticated technologies, such as infrared eye-movement cameras. As a result, studies of ASDs have only begun to quantify attachment during infancy with state-of-the-art neuroscience methodology. Nevertheless, emerging work has begun to link disrupted attachment behavior in ASDs to early-life perturbations in attention. This includes a particularly intriguing series of studies examining imitation in ASDs.

Examining the neural circuitry supporting the behavior

Considerable work delineates the underlying neural circuitry that accounts for the unique attachment behaviors in the prairie and montane vole, as depicted in Figure 10.4a. This work illustrates many of the advantages of animal models, where a precise mapping of brain–behavior associations can be achieved in a way that is not approachable with humans. In voles, species typical attachment behaviors reflect aspects of functioning in dopamine systems and in associated components of the ventral striatum mediating reward behaviors for both social and nonsocial stimuli. Moreover, changes in these behaviors following the birth of the infant are mediated by changes in oxytocin, a peptide in hypothalamic neurons that stimulates oxytocin receptors in the striatum.

Research tightly linking oxytocin to attachment behavior in voles has stimulated an extensive series of studies examining the effects of oxytocin in humans. This work suggests that oxytocin administration facilitates a number of social behaviors in humans, as it does in various rodents and nonhuman primates (Meyer-Lindenberg & Tost, 2012). This work is consistent with the long-known role of oxytocin in the facilitation of mother–infant attachment. Controversy remains concerning the nature of these effects in adults, be they related specifically to attachment or to related behaviors, such as dominance. Moreover, based on results from brain imaging studies, interest has also grown in defining the underlying neural circuit through

Figure 10.4 Work on aspects of attachment. (a) Two species of voles and associated brain slices depicting differences in the brain chemistry. (b) A task that might be used to engage the mirror neuron system of a child. Using evoked potentials, activity in the medial prefrontal cortex could be mapped, as also shown in (b) in the child's brain activation map.

which such effects unfold in humans. Data in voles focus such interest on the striatum. However, imaging work also implicates the amygdala and cingulate gyrus in oxytocin effects on human attachment behavior (Meyer-Lindenberg & Tost, 2012). This is consistent with a wealth of other research implicating these structures in a range of mammalian social behaviors, including mother–infant attachment.

Extending the current literature

Research on attachment could ultimately generate insights on comorbidity and therapeutics, much like research on cognitive control and fear. In fact, ongoing work considers the degree to which oxytocin might address underlying social deficits in ASDs, demonstrating potential treatment relevance. However, for illustrative purposes, research on attachment is described in a way that might address a distinct set of clinical questions, related to generating insights on risk. Currently, major questions exist on factors that might identify one or another infant as facing a high risk for ASDs. Available imaging data suggest that the underlying neural processes that give rise to ASDs begin to unfold in the first year of life, before a clear diagnosis of ASD can be made solely on clinical grounds (Wolff *et al.*, 2012). As such, understanding the earliest signs of aberrant social development, through careful assessment of the parent–child attachment relationship and associated brain function, may generate insights on risk prediction. Of note, ASDs are recognized to be strongly genetic conditions. Thus, any attempt to identify risk expression in attachment behavior should not be misconstrued as an attempt to identify the causes of autism, which are unlikely to involve a primary causal role for parental behavior. Rather, observations of perturbed attachment might signal the underlying presence of perturbed brain development in the child, instantiated in the brain systems that support social behavior. This shows that the causes of ASDs should be

sought in an understanding of neurodevelopment as opposed to parental behavior.

Some of the more exciting research on early ASD risk examines aspects of imitation (Marshall & Shipley 2009; Cicchetti *et al.*, 2011; Marshall & Meltzoff, 2011). Virtually within days of being born, infants show an amazing capacity to imitate the actions of others, a capacity that vanishes after a short period of infant development. Figure 10.4b presents a type of experiment where such imitative behavior can be elicited, by showing an infant a video of an adult protruding the tongue. Interestingly, this ability was once thought to be unique to humans, but emerging evidence suggests that it is shared by at least some other primates. The underlying neural architecture that supports imitative behavior is thought to involve a unique class of neurons, the so-called mirror neuron system, which supports a circuit encompassing the insula cortex as well as the cingulate, a region strongly implicated in social behavior. Technology is emerging for assessing the integrity of the human mirror-neuron system, and there is some preliminary evidence implicating dysfunction in this system in ASDs (Enticott *et al.*, 2012). Typically, in infants, this technology relies on evoked potentials, similar to the technology used to assess the ERN, as discussed in the section on cognitive control. The evoked potential reflecting mirror-neuron function also localizes to the medial area of the brain, as is depicted in Figure 10.4b. Most importantly, it may be possible to monitor the integrity of this system in human infants, before clinical signs of ASDs appear obvious. This would provide a readily quantifiable index of underlying functions in neural systems that might support attachment. As such, research using these methods could generate insights on the earliest signs of aberrant social development, as it manifests in the attachment relationship. Thus, research on attachment in ASDs may answer questions on risk prediction that cannot be addressed with currently available clinical tools.

Brain development

Defining a specific behavior in a clinical context

For this final example, behavior that is quite different from the behaviors addressed in systems neuroscience research on cognitive control, fear, or attachment is presented. For each of these first three examples, research that directly extends results from invasive studies in animal models is described. In each area, specific behaviors are defined, to be quantified in children, after the underlying neural architecture for similar behaviors already has been delineated in rodents, nonhuman primates, and adult humans. Studies in human children thereby extend a wealth of research first conducted in other organisms.

For this final example, the weight of the evidence emerges as much from brain imaging research directly with human children as it does from invasive studies in animal models. As such, research in children informs an expansion of basic research that might map the underlying neural factors that give rise to clinical observations. Moreover, the initial three examples also begin with very precisely defined behaviors already studied in basic research, as is typical in much of systems neuroscience. This final example examines a set of human behaviors that have been charted far less precisely, to illustrate the dual direction in which systems neuroscience can flow. Clearly, major insights have emerged in studies with children that extend findings in animals, as illustrated by the first three examples. However, this final example illustrates the insights that can also emerge in studies with animals that extend findings with children.

Chapter 55 describes the key behaviors of ADHD, one of which is the increased level of activity reported by observers of children with the condition, relative to their healthy peers. Not only do observers report children with ADHD to appear hyperactive, but various objective monitoring devices demonstrate differences in the motor behavior of healthy and ADHD children. Thus, for this final example, neural correlates of ADHD are described, as quantified in mean levels of recorded motor activity. With development, this aspect of ADHD has been shown to change, much as overall levels of activity also change from childhood through adolescence in typically developing children. Overall levels of activity reduce into adolescence, and reports of problematic hyperactivity symptoms in children with ADHD also become less common as these patients develop toward adulthood.

These observations, coupled with similar observations for other aspects of ADHD, have supported a view of the condition as a neurodevelopmental disorder. That is, children with ADHD might exhibit a slowing of the developmental processes that occur in healthy children to support brain development. Due to such slowing, children with ADHD may exhibit behaviors that are maladaptive largely because they are inappropriate for the child of a particular age, even though they may be appropriate for a child of a younger age. This view raises a number of corresponding questions. Does ADHD represent a manifestation of abnormal development, *per se*, or rather, is the condition

better characterized as a mere slowing of an otherwise normal developmental process? If ADHD merely represents slowed but normal development, are there factors that predict future acceleration in the pace of development, and might interventions speed this process? Alternatively, if ADHD results from abnormal rather than slowed development, does normalization of hyperactivity represent some form of atypical compensatory response, played out in aspects of brain development? For all of these questions, the neurodevelopmental perspective seeks answers in direct measures of brain development.

Examining the neural circuitry supporting the behavior

With refinements in magnetic resonance imaging (MRI) technology, clinical neuroscience began to widely apply a unique tool in the early 1990s that provided precise quantification of brain structure. While this impacted on systems neuroscience research in broad ways, the impact on child mental health research has been profound. Because MRI is safe and noninvasive, a series of longitudinal MRI investigations began to chart aspects of typical and atypical development. This work has accelerated at an amazing pace, to the point where MRI studies have examined development in thousands of children, assessed with tens of thousands of scans, conducted on the same child passing through various phases of development. Clearly, this research generates rich insights on a range of developmental questions. It has been particularly informative for understandings of ADHD.

Three major conclusions have emerged from quantitative MRI research on typical and atypical development, including ADHD. First, this research shows that brain development is an amazingly complex and slow process. Unique patterns of linear and nonlinear increases and decreases unfold in the brain's architecture. These play out over decades, lasting into the 20s. This supports the now established view of development as a process that extends relatively late in life, a view also reflected in neuroscience data generated prior to widespread application of MRI. Nevertheless, when the first MRI studies began to demonstrate these patterns, the findings were greeted with some level of surprise. Second, cross-sectional associations have been demonstrated between various clinical factors and brain structure. However, few well-replicated findings emerge in large samples, and, when they do, the magnitude of the association is not large. Thus, in the individual child with ADHD or another mental disorder, otherwise free of neurological illness, the measurement of brain structure at any one point in time is unlikely to provide clinically useful information. Finally, longitudinal data uniquely extend data contained in cross-sectional comparisons, even ones made among children of different ages. The defining characteristics of atypical brain development appear less strongly related to brain structure appearance at any specific point in time than to the overall trajectory of changes in the brain, as they play out during development.

Longitudinal research on brain morphometry in ADHD demonstrates a pattern of findings reminiscent of data on

developmental changes in hyperactivity (Shaw *et al.*, 2007; Shaw *et al.*, 2010; Shaw *et al.*, 2011). That is, while longitudinal findings are only beginning to appear, thus far, the overall patterns generally appear similar to the pattern that is observed in typical development. Here, brain development in ADHD appears to be a delayed version of brain development for typically developing children. Age-related changes in ADHD occur on a delayed timescale, months after the corresponding changes already have occurred in healthy age-matched peers. This suggests that at least some forms of ADHD may in fact be viewed as a disorder of slowed but normal brain development. Thus, in this group, remission of symptoms might reflect normalization of development. Other forms of ADHD, in contrast, which persist throughout maturation, may exhibit no such slowed but normal patterns of brain development. Finally, considerable work remains to be done; few longitudinal studies exist; and the findings appear relatively complex, in that children with ADHD represent a heterogeneous group. Some children may show typical but slowed patterns of behavioral and brain development, whereas others may show different patterns (Shaw *et al.*, 2006). As such, ADHD likely encompasses multiple disorders, from a systems neuroscience perspective. This may include some variants that represent exaggerated variations on normal development and other variants that represent more distinct expressions of atypical brain development. In the future, these variants may be defined on the basis of measures of brain development.

Extending the current literature

Current findings on brain development and ADHD can be extended through two avenues. One avenue involves an increasingly deep focus on brain–behavior associations in children followed longitudinally. The other avenue involves an increasingly deep focus in experimental animals on the factors that ultimately give rise to patterns of brain development and changes in activity, observed in ADHD and typically developing children. Here again, unlike the first three examples, for research on brain development, findings in children might stimulate a wave of research in experimental animals.

In terms of the first avenue, this will involve an extension of ongoing research. For example, future studies are likely to adopt a continued pursuit of longitudinal research that tracks in tandem changes in brain development and symptomatic expressions of ADHD. These studies also likely will acquire increasingly precise measures of brain function and behavior. This might include both the types of behavior collected in current studies, which focus largely on clinical profiles, as well as future studies that augment these clinical indices with measures more closely linked to systems neuroscience. For example, future studies might rely on paradigms such as the flanker task or other cognitive-control measures. This will allow longitudinal research on clinical-morphometry associations to be referenced more tightly to existing systems neuroscience research. Such a trend is already emerging in existing ADHD morphometry studies, which have begun to augment data on

clinical profiles and brain anatomy with data on genetics and other factors known to influence behavior through effects on brain development.

The second avenue will involve increasingly deep research in animals. As discussed in the chapter on brain imaging, the factors that produce changes in brain morphometry observed on MRI remain incompletely understood. Available basic research suggests that the findings are unlikely to reflect neurogenesis or cell death but rather are more likely to arise from refinements in dendritic arborization and axon morphology, including myelination. However, considerable more work is needed before the underlying brain processes that produce brain–behavior associations in ADHD become clinically relevant. In particular, the pattern of change in morphometry parallels the pattern of change in mean levels of activity in children with ADHD. However, it remains unclear the way in which these two sets of changes relate. This is because basic research has not attempted to reveal the mechanisms that produce these seemingly related trajectories. Invasive, experimental studies in animal models could begin to untangle the underlying neural processes that produce these parallel developmental patterns. Much as in research on extinction, as these processes become increasingly well understood, they will generate novel, clinically relevant ideas potentially pertinent to both outcome prediction and novel therapeutics.

Conclusion

This chapter attempts to accomplish three central goals. First, an introduction to systems neuroscience research is provided, emphasizing the multidisciplinary and newly emerging aspects of the area. Second, the relevance of systems neuroscience for child psychiatry and psychology is reviewed, considering the many other areas in this textbook that inform systems neuroscience thinking. Here the focus is on aspects of systems neuroscience that extend research in other domains, particularly brain imaging. Finally, four specific examples are provided to illustrate the range of clinically relevant questions that might be addressed through research in this area.

CHAPTER 11

Neuroimaging in child psychiatry

Kevin Pelphey, Brent Vander Wyk and Michael Crowley

Child Study Center, Yale University, New Haven, CT, USA

Introduction

Neuroimaging offers an opportunity to better understand psychiatric disorders via investigations of brain structure, function and/or molecular composition, and developmental change. In this chapter, we provide an overview of modern techniques that are currently used for studying the living and developing brain. We illustrate these neuroimaging methods with accessible examples of how the techniques have been used to advance our understanding of childhood psychiatric disorders. More details about specific findings can be found in the chapters devoted to specific disorders; here, we focus on the examples only long enough to bring the different neuroimaging methods to life. Finally, the chapter on systems neuroscience broadly outlines the way in which neuroimaging interfaces with neuroscience to delineate the neural correlates of developmental psychopathology. This provides a conceptual grounding for research on brain–behavior relationships, as can be quantified through imaging.

In its infancy, the study of brain function relied upon recordings of individual neurons grown in petri dishes, invasive electrodes placed in nonhuman animals, and neuropsychological studies of patients with circumscribed lesions. Several neuroimaging approaches, specifically functional magnetic resonance imaging (fMRI), electroencephalography (EEG), and functional near infrared spectroscopy (fNIRS), have emerged over the past 20 years as noninvasive methods by which we can reliably examine the function and structure of the developing human brain across the lifespan. The field can now utilize a “molecules-to-mind” approach, studying key phenomena across multiple levels of analysis including genes, brain, behavior, and the broader environmental context. These neuroimaging techniques are now routinely used to study healthy function, and dysfunction, of the brain during its maturation across development. An increasing proportion of the literature is dedicated to

describing results from one neuroimaging method or another, and much of the remaining work is now interpreted in the context of what is known, or thought to be known, about brain function. More and more, those working in the proverbial “trenches” in the field of child and adolescent mental health are expected to be informed and critical consumers of this research.

As with any research or measurement approach, a well-conceptualized research question with clearly defined constructs and operational definitions of those constructs are crucial in maximizing the interpretability and validity of neuroimaging data. But beyond this basic requirement, neuroimaging methods require specialized training and a great deal of expertise to be executed properly. However, training in utilization and interpretation of these techniques and derivative data is not currently part of routine student education and is rare even in psychiatry residency programs. As such, these techniques are most often used by child psychiatrists and psychologists in the context of large multidisciplinary research teams, with associated logistical hurdles.

Two key concepts, *contrast* and *functional resolution*, can be very helpful when evaluating functional neuroimaging approaches (Huettel *et al.*, 2009). Contrast is the intensity difference between the quantities measured by an imaging system (e.g., oxyhemoglobin levels). Contrast is determined mostly by the signal-to-noise ratio, or the magnitude of the intensity difference between quantities divided by the variability in their measurements, and applies to both temporal and spatial properties. The temporal resolution of a system refers to the ability to distinguish two events happening close in time. The spatial contrast of an approach is its ability to distinguish two truly separate effects happening close in space. No technique, neuroimaging, behavioral, or other, is useful in the absence of a valid experimental design. Functional resolution represents the ability of a measurement technique to delineate the relation between underlying neuronal activity and a cognitive or

behavioral phenomenon. Functional resolution is determined both by the actual changes that take place in the brain measure and by the ability of the scientist to manipulate experimental features to allow interpretable variation in the phenomenon of interest. Functional resolution of an imaging technique is determined by a consideration of the temporal and spatial resolutions in conjunction with the quality of the experimental design and task selection. Put simply, the selection of tasks in neuroimaging is just as critical as it is with any other method in the psychological sciences. Valid neuroimaging approaches with a high degree of functional resolution can significantly enhance the explanatory power of theories of typical and atypical social, emotional, and cognitive development in four important ways. They can (1) improve models of social, emotional, and cognitive processes via activation-based *dissociations*, that is, when two brain regions or networks show opposite activation patterns in response to the same task; (2) inform understanding of the relative timing and underlying architecture of social, emotional, and cognitive processes; (3) facilitate integration of information from diverse methodologies (e.g., genetics, lesion studies, animal models, and behavioral performance); and (4) help adjudicate between competing psychological theories.

Neuroimaging measures involve several tradeoffs. Most centrally, there is often a tradeoff between invasiveness and the degree of spatial resolution. Another tradeoff exists between temporal and spatial resolution: EEG has excellent temporal but poor spatial resolution, whereas fMRI exhibits the opposite qualities. Different neuroimaging methods provide complementary but somewhat independent measures. That is not to say that the different measures would be uncorrelated. If used to measure the same processes in the same people, especially measured concurrently, we do see convergence for some of the signals acquired across imaging modalities. However, from our perspective, a sensible approach is to triangulate on a particular construct utilizing several different methods, each appropriate to the question of interest and the developmental level of the participant.

Neuroimaging measures also have notable weaknesses, the most salient being threats to data quality and the misinterpretation of results that can follow from inaccurate data. For instance, movement artifacts not only compromise the accuracy of neuroimaging measures, but when unnoticed, they can lead to false, but plausible, conclusions. With these considerations in mind, we review several neuroimaging approaches used with infants, children, and adolescents, their advantages and disadvantages, and the exciting opportunities emerging in the field. We begin by summarizing some of the most commonly used neuroimaging methods, as well as some newer methods. We then discuss some of the critical factors that clinicians and scientists should bear in mind during the analysis and interpretation of neuroimaging research findings. Finally, we discuss the application of neuroimaging to the study of typical brain development and psychiatric disorders, with emphasis on the unique challenges associated with imaging individuals of specific age ranges.

Overview of neuroimaging techniques

Magnetic resonance imaging (MRI)

MRI takes advantage of the way in which protons behave under the influence of a strong magnetic field when bombarded with a specifically tuned radio frequency. The most common MR methods measure signals from protons in water molecules within tissue. The combined effects of the strong magnet in the MR machine and the radio frequency pulses cause protons to emit signals that are picked up by antennae in a head coil. Sophisticated computer algorithms analyze the properties of this signal for use in reconstructing three-dimensional images of the brain.

Structural MRI

In structural MRI the most common targets are the protons in the hydrogen atoms in water molecules. Since different tissues differ in the relative amount of water, the signal intensities will vary, as illustrated in Figure 11.1. This can be performed non-invasively without radiation. The term voxel, derived from “volume pixel,” denotes the smallest imageable unit. High-resolution images will have small voxels. In structural imaging, whole brain images with voxels as small as 1 mm^3 are routine, and can be acquired in as little as 5–7 min. Higher resolutions are possible with longer scanning protocols. In addition to imaging gross morphological abnormalities, researchers can measure the volume, size, shape, or depth of brain structures.

Functional MRI

Functional MRI (fMRI) is based on principles similar to those of structural MRI. However, instead of measuring water concentration, with fMRI the target is hemoglobin, the oxygen-carrying component of blood. Oxygenated and deoxygenated hemoglobin respond differently in the magnetic field. In this way, the signal generated from any given tissue provides some information about the overall level of blood oxygenation in that tissue. The resulting signal is commonly referred to as the blood-oxygenation-level-dependent signal (BOLD). Since the BOLD signal changes over time as a function of the work being done by neurons in the region, by measuring the *change* in BOLD over time we infer changes in neural activity.

Because neurons do not store reserves of glucose and oxygen, an increase in neuronal activity leads to increased perfusion and

Figure 11.1 Structural (a) and functional (b) and MR images.

elevated oxyhemoglobin in active brain areas. Thus, the ratio of oxy:deoxyhemoglobin indirectly reflects brain activity, typically in the surrounding 1–2 mm. As the neurons in specific brain regions “work harder” to perform a specific task, they require more oxygen. Because this hemodynamic response peaks around 4–6 s following the onset of neuronal activity, fMRI has this range of temporal resolution. An accessible review of these, and other issues, appears elsewhere (Huettel *et al.*, 2009). Figure 11.1 depicts a structural and functional image side by side, showing one key property of fMRI: its limited spatial resolution. This reflects unique effects of vascular anatomy and signal-to-noise properties in the two techniques. These factors typically produce fMRI voxels in the 3 mm³ range, though more advanced techniques can generate finer resolution.

A second key property of fMRI is temporal resolution. The BOLD signal response, reflecting changes in neural activity, is not instantaneous. As shown in Figure 11.2, this response takes approximately 6 s to reach a peak. In turn, the peak may remain elevated for an additional 12–16 seconds and longer if the region remains active. This sluggishness means that observed signals sum many inputs. Thus, the time course of processes commonly examined with fMRI is much more rapid than the 6 or 12–16 s that the BOLD response can take to peak.

Finally, fMRI has other notable limitations. First, research in monkeys suggests that BOLD contrast reflects mainly the inputs to a neuron and the neuron’s integrative processing within its body, and less the output firing of neurons. Second, the BOLD signal cannot provide information regarding direction of information flow, be it from feedback and/or feed-forward information flow, that is, when a region is active, fMRI cannot tell us whether the region is active because it is sending a message to another region or because it is receiving information from a region. Similarly, both inhibitory and excitatory inputs contribute to the BOLD signal such that, within a neuron, the inputs might cancel out, leaving a net zero response. In this case, theoretically important brain activity is present, but it is not detected by fMRI. An excellent discussion of these and other related issues appears in Logothetis (2008). Finally, while computing statistics to determine if a contrast is significant, we compare the magnitudes of two sample means relative to their variability. Larger differences in magnitude and lower variability means that it is unlikely the difference could have been observed

by chance. As long as a few assumptions hold, we can assign a probability p to that likelihood. By convention we do not consider a contrast significant unless the likelihood falls under a sufficiently small threshold, say $p < 0.05$. It is important to note that even when a contrast is significant, that is, the difference is not due to chance; there is still a possibility that it is. Incorrectly asserting that a difference, or contrast, is real when it is not, is called a type I error. If we only make a single comparison, then a type I error is unlikely—it’s just the probability p chosen as our threshold. Unfortunately, each time we make another comparison, there is another chance for a type I error. As more and more comparisons are made, the likelihood of a type I error goes from small to certain.

This is the problem with multiple comparisons, and it is ubiquitous in fMRI. The statistical models from which contrast maps are derived can be computed for each voxel in the brain. Specific regions can be interrogated using delineated regions of interest, but most studies are not or cannot be this selective. Since there are tens of thousands of individual voxels in the brain, this means that the analyses will require tens of thousands of statistical contrasts, and consequently tens of thousands of chances to make a type I error. Fortunately, there are a number of methods that researchers can use to correct for multiple comparisons. These methods can be quite technical, but the underlying concepts are fairly straightforward (see Nichols & Hayasaka, 2003; Bennett *et al.*, 2009 for further review and discussion). Uncorrected results, even when published in prominent journals, should be viewed skeptically until they can be replicated.

Notwithstanding these limitations, fMRI does help inform understanding of childhood psychiatric disorders. One set of insights relates to neural correlates of risk. For example, fMRI can measure neural specialization for social information as it relates to risk for autism spectrum disorders (ASD), using biological motion social perception paradigms. Point-light displays track the way in which people move, conveying with a simple stimulus array specific kinds of motion (e.g., walking or dancing). In an fMRI study from our group (Kaiser *et al.*, 2010), 4- to 17-year-olds viewed coherent and scrambled point-light animations of biological motion. Three groups were studied: (i) children with ASD, (ii) unaffected siblings of children with ASD (UAS), and (iii) typically developing children (TD), revealing three kinds of brain activity: (i) perturbed state activity, occurring only in ASD; (ii) perturbed trait activity, occurring in ASD and UAS; and (iii) compensatory activity, where the UAS group differed from the two other groups. Perturbed state activity in this particular task is a correlate of disruption in brain circuitry in ASD, whereas perturbed trait activity could be regarded as an ASD endophenotype (Gottesman & Shields, 1973). Compensatory activity might reflect mechanisms by which UAS overcome risk. In each case, these observations require a direct assessment of brain function, made possible through fMRI, illustrating the power of fMRI and indirectly providing ideas about novel treatments.

Figure 11.2 Canonical hemodynamic response.

Other fMRI techniques provide more direct clues about treatment. For example, considerable interest focuses on fMRI neurofeedback where much of the research so far has targeted pain. Scheinost and colleagues (2013) extended this technique to target subclinical contamination fears by teaching individuals to reduce their anxiety by altering their BOLD signal patterns. In this study, a region of the orbitofrontal cortex associated with contamination anxiety was targeted, which subjects learned to modulate in a way that simultaneously improved symptoms associated with contamination anxiety and the brain and behavioral changes were correlated. These findings have the potential to support a strong translational connection between research and clinical practice, as they provide an observable marker of treatment working, for whom it works best, and that it can be observed to work at a biological systems level, thereby highlighting the potential for individualized medicine.

Structural and functional connectivity

Diffusion tensor imaging

Since no region of the brain acts in total isolation, it is important to understand how brain areas communicate. To this end, researchers have used both structural MRI and fMRI methods. Diffusion tensor imaging (DTI) is a structural method that measures the momentary diffusion of water through the brain. In unconstrained regions, such as the ventricles, water diffuses isotropically, but in nerve fibers, water diffuses in some directions more than others. By measuring diffusion along such fibers, nerve fiber integrity can be mapped with DTI. However, if axons within a voxel are not traveling along the same path, the average diffusivity will appear isotropic. This “fiber-crossing problem” limits the ability to detect structural connections in less spatially organized areas of white matter.

To illustrate the power of this method, consider the results of a DTI study showing that the developmental trajectory of white matter tracts is different in babies who go on to develop ASD versus those who do not (Wolff *et al.*, 2012). The available evidence suggests that early, overt symptoms of ASD usually emerge late in the first or early in the second year of life. Wolff and colleagues (2012) prospectively traced white matter fiber tract organization from 6 to 24 months in high-risk infants who developed ASD by 24 months. Infant siblings of children with ASD who went on to receive a diagnosis of ASD at 24 months of age had distinct brain patterns at 6 months and abnormal neural development from 6 to 24 months. These results are particularly striking because they demonstrate that aberrant development of white matter pathways may precede the manifestation of autistic symptoms in the first year of life. Biomarkers like these, especially if paired with information from genetic and behavioral screens, could potentially help identify children with ASD before symptoms appear.

Functional connectivity

Two regions are functionally connected if their corresponding BOLD signals correlate in time. The logic is that, all else being

equal, if two regions are communicating then such fluctuations will correlate. As with any correlation, functional connectivity may reflect effects of third variables. As an example, upon viewing a face we might observe correlations in the BOLD signal in two brain regions. However, these correlations may be due to communications occurring over connections between the regions, or both regions could be responding to the third variable (the face stimulus). Nevertheless, the ease of assessing resting state functional connectivity has led to widespread use of the technique.

Electrophysiology

Electroencephalography

In contrast to fMRI, EEG and event-related potentials (ERPs) directly measure the firing of groups of cortical neurons. During information processing, neuronal activity creates small electrical currents that can be recorded from noninvasive sensors placed on the scalp, providing precise information about the timing of processing and clarifying brain activity at the millisecond pace at which it unfolds. The high temporal resolution of ERPs complement the high spatial resolution of fMRI. Both have critically informed our understanding of typical and atypical development. FMRI measures have helped identify some of the neural circuitry supporting various psychological processes including social cognition, emotion regulation, face recognition, working memory, and attention. These studies have also provided insight into whether certain regions of the brain are differentially activated at specific points in development. ERP measures inform our understanding of the timing of the stages of psychological processes and help identify the distinct functions that each brain region performs at particular points in time as a psychological task unfolds. For example, several classic fMRI studies independently identified a region of the brain called the “fusiform face area” in the posterior fusiform cortex of the ventral temporal lobe that selectively responds to faces (e.g., Puce *et al.*, 1996; Kanwisher *et al.*, 1997). Electrophysiological measures reveal that this region is engaged in several distinct psychological processes relevant to face processing at different points in time (e.g., Bentin *et al.*, 1996). At approximately 170–200 ms after the appearance of a face, this region exhibits activity supporting the perception of a face as a face, instead of another category of object. Slightly later, at approximately 300–400 ms, another wave of activity that has been linked to the recognition of the face’s identity (e.g., a stranger versus a friend or “that is the Queen of England.”) is observed. Finally, at 450 ms and beyond, activity supporting the perception of the emotional expression displayed on the face (e.g., anger versus happiness) is observed in the same cortical area. The classic monograph by Luck (2005) is an outstanding introduction to and tutorial about EEG/ERPs.

Examination of the electrical signals captured at the scalp reveals fluctuations or waves called oscillations. These oscillations arise from rhythmic postsynaptic potentials generated by populations of cortical pyramidal neurons. The rhythms underlying the EEG signal can be decomposed into constituent

frequencies reflecting various rates of brain oscillation. EEG oscillations are characterized by their frequency in cycles per second (Hertz, Hz). For instance, EEG alpha refers to frequencies typically between 8 Hz and 12 Hz. With an approach called fast Fourier transform (FFT), the proportion of frequencies that make up the signal can describe the EEG signal. Other common EEG frequency bands are labeled delta (1–3 Hz), theta (4–8 Hz), beta (13–24 Hz), and gamma (25–100 Hz). These frequencies coincide with various mental states (e.g., sleep, awake, at rest, etc.), and can also be examined by their patterns (frontal alpha asymmetry), ratios (theta/beta ratio), and changes across contexts (alpha suppression, also known as mu suppression). Oscillatory activity derived from the FFT does not provide information about the timing of neural events, as is the case for ERPs.

ERPs are computed as the average signal across events, locked to a stimulus or action. Thus, tasks designed to acquire ERPs tend to be repetitive, allowing for sufficient numbers of measurements to resolve a reliable ERP. Importantly, ERPs capture the stimulus- or response-driven partial phase alignment, and power increases in the ongoing EEG brought about by the event (Le Van Quyen & Bragin, 2007; Sauseng *et al.*, 2007). Developmental ERP studies are appealing because they are relatively low cost to collect, provide measurement of actual neuronal activity, and are interpretable based on previous cognitive neuroscience studies. The ERP reflects a series of positive- and negative-going peaks thought to reflect stages of sensory and cognitive processing. Different types of experimental tasks are used for eliciting various ERPs; for instance, tasks that require inhibiting a response or tasks that present a novel stimulus among repetitive stimuli. One of the most commonly assessed ERPs is the P300. In ERP nomenclature, the “P” indicates a positive ERP peak and the “300” reflects that the response happens at approximately 300 ms. Other ERPs are labeled for their function, such as the error-related negativity (ERN), which occurs in response to simple cognitive errors, such as responding when a response should be withheld. Although ERPs are not known for their spatial precision, they tend to appear in different regions on the scalp. For instance, faces tend to elicit an N170 response that appears bilaterally in temporal-parietal scalp regions. In psychiatry, ERPs have been used to characterize the neural correlates of information processing and underlying pathophysiology in most neuropsychiatric disorders. They can also be used as indicators of risk or indicators of drug effects and behavioral treatment effects.

ERP measures have revealed subtle differences in processing of social information at the neural level in children at risk for ASD. The lack of reliable indicators of ASD during the first year of life has been a major impediment to early intervention: in the absence of a firm diagnosis until behavioral symptoms emerge, treatment is often delayed for two or more years. Given its strong social components, Elsabbagh *et al.* (2012) hypothesized that neural sensitivity to eye gaze in early infancy would predict later development of ASD. Notably, there is little behavioral evidence of early disruption in eye gaze processes in infants

later diagnosed with the disorder. The researchers recorded ERP while 6- to 10-month-old high-risk infants (siblings of a child with ASD) viewed faces with dynamic eye gaze directed either toward or away from them. Neural responses to dynamic eye gaze shifts during the first year predicted clinical outcomes at 36 months, despite similar gaze patterns measured by eye tracking. The authors concluded that neural responses to eye gaze in the first year of life reflect disruptions in basic developmental processes linked to the later emergence of ASD.

This finding illustrates that measures of brain function can index developmental and individual differences in underlying processing mechanisms that are otherwise invisible and impervious to study because they do not produce overt behavioral evidence. EEG measures can be leveraged even in very young infants as “neural signatures” of processes that are not available to observation or verbal report. Further, some neural signatures, for example, ERP responses indexing face perception, may be remarkably consistent across the lifespan, allowing researchers to measure certain aspects of socioemotional processing using identical neurophysiological methods even when major developmental changes demand alterations in other measurement strategies (e.g., a shift from behavioral observation to verbal report).

ERPs reflect the aspects of the EEG signal that are in phase (colloquially “in sync”). Any “out of sync” electrical activity tends to be averaged out. ERPs also do not speak directly to which frequencies underlie the brain process in question. In the past 10 years, implementation of advanced signal processing techniques such as short-time Fourier and wavelet transform can investigate the EEG signal in terms of frequency, power, and phase. This approach, broadly conceived as event-related brain dynamics (Makeig *et al.*, 2004), can characterize the EEG signal in terms of frequency, power, and phase (time). Importantly, characterizing oscillatory dynamics in this way probably more closely reflects the activity of underlying neuronal assemblies (Buzsáki, 2006).

Event-time-locked frequency analyses of EEG allow for the measurement changes in EEG power and phase synchrony, across trials, on a millisecond time scale. In particular, event-related spectral perturbations (ERSPs) temporally sensitive indices of the relative change of mean EEG power from baseline associated with stimulus presentation or response execution. Unlike ERPs, ERSPs capture changes in spontaneous EEG activity that occur across several frequency spectra and are sensitive to fluctuations that are temporally stable (Makeig, 1993; Makeig *et al.*, 2004). The value of ERSPs becomes clearer when we view them against the backdrop of a traditional ERP approach. Because ERPs involve signal averaging, we cannot say precisely which frequencies underlie them, only the range of frequencies we started with before averaging. By examining ERSPs we can directly examine which EEG frequencies underlie responses to experimental events, and by extension determine which frequencies underlie ERPs. A well-known example involves the ERN, where Luu *et al.* (2004) showed that

the error-related negativity ERP can be largely accounted for by an increase in evoked (event-related) theta power following an error. Although ERSPs are able to capture induced power changes, not revealed in typically averaged ERPs, they do not reveal details about the synchrony of the event-related EEG signals, discussed next.

The inter trial coherence (ITC) reflects the degree of synchronization of the EEG for events (e.g., stimulus or response) in a task. Analogous to a correlation coefficient, intertrial phase values refer to the degree of association across trials, ranging from 0 to 1. Thus, for a range of frequencies, a larger value indicates greater phase synchrony (more consistent phasic activation) for the frequencies in question. ITC is assessed at a single location or region and thus reflects “temporal coherence,” to be distinguished from “spatial coherence,” assessed across brain regions. As one example illustrating the value of ITC, on a simple go/no-go task, adolescents with ADHD were found to have comparable ERN ERP responses compared to controls (Groom *et al.*, 2010). However, controls did show greater theta (4–8 Hz) phasic consistency (ITC) in the neural response to errors, which was correlated with a measure of performance (greater d-prime)—ITC was unrelated to performance in the ADHD group. This finding led the authors to suggest that less consistent phasic activation of the neural response to errors might underlie the poorer inhibitory performance (lower d-prime) seen in patients with ADHD, a conclusion that could not be drawn from the ERP data.

Magnetic resonance spectroscopy

Magnetic resonance spectroscopy (MRS) is another imaging modality that relies on the same basic principles of physics used to conduct structural and functional MRI studies. Thus, strong magnets and radiofrequency waves are used to non-invasively assess functional aspects of the brain. The unique feature of MRS relates to the sensitivity of particular chemicals to distinct resonance frequencies that can be detected through MRI. This quantifies the level of one or another chemical in a voxel. However, there are restricted numbers of compounds that can be assessed with MRS, relative to more invasive chemical techniques, like positron emission tomography (PET) (though PET is much too invasive for routine use as a research tool, as discussed later). Typically, these compounds vary in their arrangements of carbon and proton atoms.

Magnetoencephalography

Magnetoencephalography (MEG) is another, less frequently employed, but powerful functional neuroimaging technique. In MEG, brain activity is mapped by recording the magnetic fields resulting from brain electrical activity. MEG is recorded using very sensitive magnetometers. The most common magnetometers are superconducting quantum interference devices (SQUIDs), which are capable of measuring extremely subtle magnetic fields. The signals acquired via MEG resemble those acquired via EEG, in terms of their oscillatory pattern.

Thus, many of the analytic approaches just described for EEG, including signal averaging and oscillatory analyses, can also be done with brain signals acquired through MEG. However, at least for the brain’s cortical surface, MEG is able to assess brain activity based on such signals with superior spatial resolution. A comprehensive introduction to MEG can be found in Hansen *et al.* (2010).

Positron emission tomography

Like MRI, PET can produce three-dimensional images of brain structural and function. However, unlike MRI, PET is invasive, as it detects gamma rays emitted from injected radioactive tracers as they decay. Because many neurochemicals can be altered to create radiotracers, PET is particularly well suited for examining functional neurochemistry, provided that an ethical justification exists for such an examination in a child. Thus, while MRS is less invasive than PET, PET can currently quantify a much broader range of chemicals than MRS. Increased metabolic activity, similar to assumptions made in fMRI, is correlated with increased neural activity. Thus, regions in which the tracer concentration is high, measured as locally increased radioactivity, represent highly active regions. In addition to the measure of metabolic activity, some tracers can bind to specific neuroreceptors, such as dopamine receptors (Catafau *et al.*, 2010). Differences in the amount of tracer then indicate differences in the receptor density, which may have profound implications for understanding disease processes in a variety of mental health conditions.

Functional near infrared spectroscopy

fNIRS uses lasers instead of magnetic fields, but like fMRI, it also measures changes in hemoglobin. Similar to a pulse oximeter, fNIRS works via a laser emitting light at one point and a receiver detecting the amount of unabsorbed light at a nearby point. The wavelength of the light is tuned such that the regional oxygenated or deoxygenated blood flow can be inferred from the amount of light absorbed. Although the scalp and skull are opaque to visible light, they are almost transparent to light in the near infrared range (800–2500 nm). Because blood absorbs light photons differently depending upon how much oxygen is present, shining a near infrared light into the head and measuring the intensity of the exiting light can reveal the differential absorption of light as a function of blood oxygenation level, thus providing an indirect measure of brain activity at and just beneath the cortical surface. fNIRS appears to be quite promising for enhancing our understanding of the developing brain particularly in very young children, as well as in older children and adults (Gervain *et al.*, 2011). fNIRS is less sensitive to motion and can be utilized in less-constrained, more ecologically valid experimental paradigms than fMRI and EEG/ERP. Furthermore, by measuring both oxygenated and deoxygenated hemoglobin in brain tissue, fNIRS provides two distinct (but correlated) indicators of neural activity, which

allows for absolute measures as opposed to only baseline-relative measures and thus increases its flexibility (Gervain *et al.*, 2011).

A surprisingly large number of studies have used fNIRS to examine social and emotional processes in typically developing neonates to toddlers. Several have focused on the development of face processing. At 4 months, the temporal cortex of infants activates selectively to faces relative to other objects (Csibra *et al.*, 2004; Blasi *et al.*, 2007). At 6 months, infants exhibit increased activity to upright versus inverted faces in the right temporal cortex (Otsuka *et al.*, 2007). At 8 months, activity in temporal regions is observed independent of viewing angle (Nakato *et al.*, 2009). These findings regarding the localization of neural signatures of face processing in infants are unique to fNIRS, particularly the ability to localize activity in infants who are awake and actively attending to visual displays. Researchers investigating responses to dynamic social stimuli such as eye and mouth movements have identified bilateral superior temporal and inferior frontal cortical activations in infants starting as early as 4 months, consistent with activation observed via fMRI in older children, adolescents, and adults in response to the same kinds of stimuli (Grossmann *et al.*, 2008; Lloyd-Fox *et al.*, 2009). See Gervain *et al.* (2011) for a comprehensive review of fNIRS studies of infants.

One might wonder why everyone does not use fNIRS all the time. It is less sensitive to motion and can be utilized in less-constrained, more ecologically valid social paradigms. From the perspective of head motion, the observation is correct. But there are always critical tradeoffs with functional neuroimaging techniques. Even though fNIRS is more resistant to head motion, it only measures activation at the cortical surface. The light used to image brain function does not return to the optodes from deeper cortical areas and, critically, subcortical areas. Many of the key social and emotional brain areas are deep within the cortex or are part of the limbic system, and thus are invisible to fNIRS. Moreover, the more hair on the participant's head, and the thicker the skull, the more difficult it is to use fNIRS; it works best in infants and young children, and aging men.

Imaging genomics

Inspired in part by advances in measurement technologies, developmental scientists are now actively investigating the complex transactions driving developmental changes across multiple levels of organization, including the environment, behavior, cognition and emotion, brain, and genes (Gottlieb, 1992), operating in a transactional bidirectional fashion. Use of *in vivo* pediatric brain imaging techniques in this context offers an additional opportunity for developmental, multilevel analysis across the full lifespan.

Functional neuroimaging offers a potential means by which associations between genetic risk factors and the activity of specific brain circuits, during processing of discrete stimuli or performance of distinct behaviors, can be investigated. There is growing interest in the identification of brain structural and functional changes associated with genetic risks that are being

identified including common allelic risks and high penetrance rare mutations, although there is a need to guard against the possibility of type I errors that arise from multiple testing (see Chapter 24). Replications are required, as with any method. Ideally, associations between gene variants and regional patterns of brain information processing will not only help elucidate the biological mechanisms underlying previously demonstrated gene links with behavior but will also direct attention to new behaviors that are mediated by genetically influenced brain systems and vice versa.

To illustrate, consider a study by Durston and colleagues (2008) on the dopamine transporter (DAT1) gene and attention deficit/hyperactivity disorder (ADHD). Genetic studies had originally suggested a link between the DAT1 gene to ADHD, but findings have been mixed (see section on candidate genes and Chapter 24). Nevertheless, we use this as an illustration. Dopamine transporters are highly expressed in the striatum. In fact, some stimulant medications shown to be effective in ADHD are believed to exert their effects by blocking dopamine transporters in the striatum. The authors investigated the association between one gene variant in the gene encoding DAT1 and brain activation patterns in ADHD. They studied sibling pairs discordant for ADHD and typically developing controls using fMRI and a go/no-go (press a button for “go” stimuli and inhibit a response for “no-go” stimuli) paradigm. The DAT1 genotype was associated with the level of activation in the striatum. As more robust genetic findings are emerging (see Chapter 24), this approach serves as an illustration of the type of research that might be used to assess risk-allele-associated neural signatures.

Despite its promise, the application of imaging genetics to our understanding of typical and atypical development is currently limited by at least three major challenges: (1) most gene variants, with the exception of rare, highly penetrant mutations, have small effects on behavior, and prior imaging studies are likely to have overestimated effect sizes for the brain, due to the challenge of handling multiple testing; (2) imaging genetics remains inherently correlational and suffers from an absence of detailed analysis of mechanisms; (3) all imaging genetic studies to date have focused on cross-sectional samples of adolescents and young adults in racially and culturally homogeneous samples. There is a great need (and opportunity) for longitudinal designs to examine the influence of robust genetic risk variants on developmental trajectories of the social brain and social behavior in diverse populations. If these challenges can be addressed, imaging genetics research could help increase our understanding of how genetic variation interacts with the environment to shape the development of the brain and the corresponding effects on behavior.

Analysis and interpretation of imaging data

Study and experimental design are important points of consideration in any investigation of typical and atypical development.

Brain imaging research is no exception. Indeed, all of the well-known issues that need to be addressed in standard psychological or psychiatric experiments need to be addressed in brain imaging research as well. However, neuroimaging research also imposes unique design constraints discussed in the next section. We consider two issues: the study and the experiment. Conceptually, the study level addresses the question of “who” is being studied, and the experiment level addresses the question of how.

Study level design considerations

Within-subjects designs

Imagine we were interested in whether activation in dorsal lateral prefrontal cortex (DLPFC) is higher during greater cognitive load. To answer this question, we create an experiment where we scan people while they do a task with two levels of difficulty, and compare whether activation in the DLPFC was higher when they were doing the easy level or the hard level. This is a within-subjects design, as is used in many psychiatric brain imaging studies, since each participant receives each condition, and the test is between each person’s activation on one condition relative to the other.

Between-subjects designs

Many important questions require between-subjects designs, where not all participants receive all treatments. This includes studies between different groups (autism spectrum disorder versus typical development) or different treatments (cognitive behavior therapy versus waitlist). If the between-group factor is one that is under the experimenter’s control, a true experiment, then they can deal with potential group differences using random assignment. For example, in a neuroimaging study of treatments, individuals could be randomly assigned to one treatment or another. So long as the sample sizes are large enough, the logic of random assignment allows the researcher to be confident that group differences should be insignificant. This is true of factors that might impact neuroimaging data. However, it is often the case that studies of interest to psychiatrists are subject to biases from confounds (see Chapter 12). Participants are not assigned to groups by the researcher. For example, we do not assign a child to an anxious group, or to a specific age. The limitations of a design must be considered in the interpretation of neuroimaging results as they are with other studies (see Chapter 12) with particular emphasis on those aspects of group-level differences that impact brain data. A crucial difference between many psychiatric populations and typically developing controls is the ability to comply with instructions that ensure a good quality scan (e.g., remaining still for the duration of an fMRI scan). This point is taken up at length later.

Cross-sectional versus longitudinal studies

Tension between cross-sectional and longitudinal designs exist in neuroimaging as in other areas of developmental research. Cross-sectional studies are quicker and less expensive than

longitudinal studies. However, only longitudinal studies map individual developmental trajectories. This approach may be more informative than observed differences in age-specific group averages—especially in a dynamic system such as the developing brain.

Test-retest reliability

An important consideration in evaluating longitudinal fMRI studies is test-retest reliability. Test-retest reliability refers to the ability of a measure to produce systematic results when repeated under similar conditions. If a specific experiment does not generate reliable results across time, its utility as a longitudinal method is limited. Unfortunately, the available studies suggest that while the test-retest reliability of fMRI for adults is quite good, it is poor to fair for younger, school-age children and adolescents (e.g., Koolschijn *et al.*, 2011; van den Bulk *et al.*, 2013).

Experiment level design considerations

Since many of the questions regarding brain function overlap with psychological questions, the experimental paradigms often overlap as well. Many tasks tapping executive functions, language, memory, and so on have been adapted for use in neuroimaging. However, due to the nature of fNIRS and fMRI, particularly the relatively sluggish responses measured, experiments often need significant modification or may not be suitable for neuroimaging.

Block designs

A popular design in fMRI experiments is the block design. In block designs, experimental stimuli are presented, perhaps repeatedly, in a block lasting 12–30 s. For example, a researcher studying the response to emotional facial expressions might present 10 angry faces, each lasting 2 s, in a given block. Repeated presentation of a region’s preferred stimulus type can drive activation very strongly, and the long duration allows for the full evolution of the sluggish hemodynamic response. This makes block designs quite powerful from a statistical perspective. However, block designs may not be very naturalistic and designing a blocked version of traditional trial-based psychological experiments may not be feasible in many cases. In addition, different regions of the brain, such as the amygdala, may be more sensitive to habituation than others, and the block design also is sensitive to a number of confounds.

Event-related designs

In event-related designs, individual trials of a given experimental condition are normally presented one by one, making them more analogous to traditional psychological designs and less sensitive to confounds that plague the block design. Individual trials may be brief, so to achieve sufficient power requires a large number of trials. However, even then the spacing between trials must be sufficient to allow for the hemodynamic response to evolve. Researchers differentiate between event-related designs

that use long (16 s or more) and short inter trial intervals (2–8 s). The former, termed slow-event-related designs, permit the BOLD signal to return to a baseline state after the end of stimulation. With the latter, termed fast-event-related designs, the BOLD signal does not necessarily return to baseline between trials. Special analysis strategies must be used with these designs because the observed signal may be driven by contributions from many overlapping trials. The hemodynamic response normally takes 12–16 s after stimulation ends to completely “relax” and return to baseline. If we present stimuli more quickly than every 12–16 s, we have to account for the fact that the hemodynamic response observed at any one point in time may reflect influences from both the current and previous stimulus.

Motion and motion artifacts

Participant motion can compromise analysis. fMRI data for a single volume is acquired over some window of time, usually 2 s, and typically with a predetermined scan slice sequence (i.e., starting at the bottom of the brain and moving up). Participant motion during the acquisition of a single volume can mean that certain brain regions may be missed or imaged more than once. Motion across volumes has the effect that intensity changes as a function of time, which may be driven by changes in the intensity of the underlying structure and not BOLD changes (Figure 11.3). If these changes are correlated with experimental manipulations, spurious “activity” can be observed.

When a participant moves, that motion typically affects all observed voxels, which in turn causes false correlations in the BOLD signal. Since functional connectivity is fundamentally a measure of correlations among BOLD responses, it is particularly susceptible to motion artifacts. Special care needs to be taken to compare motion estimates across different groups in between-subject designs. Different populations may be less able to control their motion in the scanner. Younger children or children with mental health disorders may not be willing or able to stay still over extended periods of time, especially in

the context of (boring) psychology experiments. Recognition of this issue in psychiatric neuroimaging has led to an increased interest in developing better methods for dealing with motion differences in statistical models.

Recent work has shown, however, that even tiny movement artifacts (0.004 mm) can lead to insidious biases in fMRI analyses and potentially to false conclusions even without causing noticeably “blurry” images (Power *et al.*, 2012; Van Dijk *et al.*, 2012). The results of two sets of papers representing groundbreaking advances in developmental science illustrate this dilemma. First, via highly innovative, mathematically complex analyses of resting-state functional connectivity data, two papers reported that short-range brain connections are robust in school-age children and weaken into young adulthood, whereas long-range connections begin weak in children and strengthen over time (Fair *et al.*, 2008; Dosenbach *et al.*, 2010). However, recent work demonstrates that these findings actually result from uncontrolled age differences in head motion, with younger children moving more than older children, adolescents, and adults (Power *et al.*, 2012; Van Dijk *et al.*, 2012).

Normalization and group comparisons

Every brain is unique. The specific location, size, and shape of any given anatomical landmark differ from person to person. This poses a challenge for aggregating data across many individuals. Normalization refers to the method of warping a given participant’s brain data into a common space or to fit into a common template (Talairach & Tournoux, 1988; Thomason *et al.*, 2013). These routines are usually automated and operate on a high-resolution anatomical scan. Having computed a normalization solution, it is applied to the functional data. Once in a common space, the data can be effectively compared and analyzed across groups.

However, most normalization methods have been developed for application to studies of adults. Automated normalization routines will work best on those brains that are most anatomically like adult brains (older children) and potentially less well on brains that are anatomically different (younger children). Biases introduced by developmental changes in anatomy may mask or exaggerate changes in function. New age-dependent templates are becoming available as larger cohorts of children are entered into databases; however, they are not yet part of standard practice.

Difference maps

Colorful images of patterns on images of brains, often accompanied by descriptions of the activations they represent, are fixtures of both the scientific literature and the lay press. It is important to recognize that many of these images represent areas that show a statistically significant difference between conditions and groups. For example, in Figure 11.3, we see a bright patch in the ventral temporal cortex during a face processing task. It would not be uncommon to have this pattern described as “activation to faces” in support of the argument that this is a face-specific

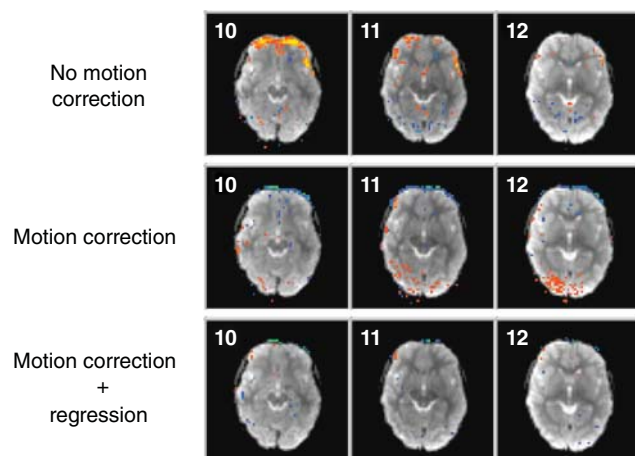

Figure 11.3 Statistical parameter maps with (a) and without motion correction (b).

region of the brain. But bearing in mind that these are often difference maps, we could justifiably ask, “activation to faces **relative to what?**” Has this region come from a comparison to fixation, or to some control condition? If there was a control condition, what was it? What was it controlling for? This information should be presented in primary literature, but often is lost in the translation to secondary and tertiary literatures. In this case, the control condition is houses. The region in red on the figure represents a region for which the difference Face – House > 0 is probably true. However, from this result alone a researcher cannot claim that this region does not respond to houses at all.

There are a number of regions in the brain whose characteristic pattern of activation is actually to *deactivate* when external stimuli are presented. This network, sometimes referred to as the task-negative or default mode network, includes the medial prefrontal cortex and the precuneus. These regions are implicated in a number of functions that are of interest to pediatric psychologists and psychiatrists such as mentalization, self-referential processing, reflection, and autobiographical memory. Difference maps for these regions may reflect difference in relative deactivation during the scan.

Conclusions

Neuroimaging is still a new research tool in child psychiatry, though an increasing number of studies will embrace the tool in coming years. A critical consideration is how they relate to observational and verbal report measures of the same or related constructs. Studies that use these new measurement approaches in conjunction with well-understood paradigms and measures are essential to establishing the validity and utility of their empirical findings (e.g., Pfeifer & Peake, 2012). Looking ahead, researchers in child psychiatry are now poised to study directly, in humans, bidirectional transactions among levels of analysis from genes, to brain, to behavior, and the environmental context. Methodological advances provide novel insights into longstanding questions while generating a vast array of new questions.

We are quite optimistic for the future of neuroimaging in child psychiatry. We expect that future research will enable new approaches for studying the neural mechanisms of response to potential behavioral and/or pharmacological treatments. The future will also provide opportunities to assess treatment outcomes at the neural systems level, identify neuroimaging-derived biomarkers that may serve as moderators of treatment response, identify changes in brain mechanisms that may mediate behavioral changes, and determine early efficacy indicators. Work in this area could also inform the ability to predict response to treatment and detect subtle changes that are not yet evident in behavior. As such, neuroimaging studies will contribute to the refinement of efficacious interventions, consistent with the priority of creating individually tailored interventions customized to the behavioral, neural, and genetic characteristics of a given person.

C: Epidemiology, interventions and services

CHAPTER 12

Using natural experiments and animal models to study causal hypotheses in relation to child mental health problems

Anita Thapar¹ and Michael Rutter²

¹Child and Adolescent Psychiatry Section, Institute of Psychological Medicine and Clinical Neurosciences, Cardiff University School of Medicine, UK

²Social, Genetic and Developmental Psychiatry (SGDP) Research Centre, Institute of Psychiatry, Psychology and Neuroscience, King's College London, UK

Introduction

There is enormous scientific and public interest in identifying causes of child mental health problems. However, this pursuit is challenged by multiple factors that threaten the validity of claims about causality. Furthermore, mental health problems and related traits have a complex etiology, as is typical of most common medical disorders. Multiple risk factors contribute and no single risk is necessary or sufficient to cause disorder. Researchers and practitioners need to be aware of these threats and complexities before making causal inferences. As we will discuss, the types of challenges encountered are not simply overcome by the use of ever larger, observational studies, even if they are longitudinal cohorts or through meta-analyses of multiple studies.

We begin this chapter by explaining key terms that are used with respect to the investigation of causal hypotheses. We then describe some of the key problems encountered in the search for causes and explain why natural experiments are useful and what they are. The focus will be on the growing range of different types of natural experiment, with the emphasis on principles and strategy, assumptions and limitations rather than the details of each. We also provide selected illustrative findings. This chapter draws heavily on a report on this topic by the Academy of Medical Sciences (2007) and a series of papers by Michael Rutter (Rutter 2007, 2012; Rutter & Thapar, in press). We then adopt a similar approach to animal models. Interestingly, the major interest in both natural experiments (Campbell & Stanley, 1963) and animal models (Rosenzweig *et al.*, 1962) arose at about the same time in the middle of the last century. Both were concerned about providing rigorous testing of the causal

inference but they faced somewhat different challenges. Natural experiments necessarily involved unusual circumstances and it was necessary to consider the extent to which findings could generalize to more ordinary situations. For example, did special biases arise in the study of adoptees? Animal models had to examine the assumptions involved in the experiments but also had to determine whether the parallels with humans were valid. However, as we discuss, animal models have three main advantages: (1) the ability to study long-term effects (possible because of the much shorter life span of the animals used); (2) the direct testing of the possible causal effect; and (3) the combination of behavioral and brain data providing the ability to investigate the brain processes involved. Accordingly, it is appropriate to consider the two strategies together—as we do here.

The key terms cause, correlate, risk factor, causal risk factor, mediator, and moderator are used ambiguously and this has been comprehensively discussed by Kraemer *et al.* (1997, 2001); these are summarized in Table 12.1. A causal risk factor is one that, if changed, would alter the outcome and the implication is that the burden of disorder would be reduced. As we have already highlighted, there are considerable challenges to identifying true causal risk factors, and no design is perfect. This underpins two key messages of this chapter. It is critical to consider alternative explanatory hypotheses when a risk factor appears to be causal. It is also important to make use of designs that have the potential to disprove hypotheses and not simply focus on repeatedly generating supporting evidence. Any given research design has its own set of assumptions and limitations and faces different threats. Unequivocal proof of causality is difficult if not impossible to generate. Thus, a convergence of findings across different types of natural experiment lends greater confidence toward supporting or refuting causal hypotheses.

Table 12.1 Key terms and their conceptual meaning.

Risk	Probability of an outcome in a given population
Risk factor	A measurable exposure or agent that precedes the outcome and is statistically associated with it
Correlate	Meets criteria for risk factor but is measured at the same time or after (thus not known to precede outcome)
Causal risk factor	A risk factor that changes risk of outcome when manipulated
Mediator	A variable via which a causal risk factor exerts its influence on outcome
Moderator	A third variable that influences the association between a risk factor and outcome

Why natural experiments are useful

While the observation of association and identification of risk factors is a start, it is not enough. That is because there are many noncausal explanations for association.

First, there is the problem that risks are not allocated randomly to individuals. Thus, associations with outcomes can simply reflect correlation or association with factors that influence the origins of the risk factor. These can include the effects of social selection and other types of “allocation” bias. Genetic influences on environmental exposure (gene–environment correlation) are also an important consideration. For example, are the higher rates of psychopathology in children born to teenage mothers causally explained by being reared by a young mother or does it reflect something about selection via the attributes of teenagers who become pregnant at this age? Is the elevated rate of antisocial behavior in offspring of mothers who smoke cigarettes in pregnancy because of fetal exposure to the toxic effects of cigarettes during intrauterine life? Or rather, does the association reflect something about selection through the genetic makeup and/or social background of mothers who are unable to quit smoking in pregnancy? We know that mothers who smoke in pregnancy differ on multiple, relevant measured characteristics from non smokers and from those who quit (Pickett *et al.*, 2009).

Another problem lies with assuming that a risk factor is causal when it is in fact a proxy risk; that is, it encompasses some other variable that has the causal risk effect. For example, while “broken homes,” on the face of it, appear to be a risk factor for child psychopathology, in the sense that it can temporally precede difficulties, it behaves as a proxy for discordant relationships and impaired parenting, and it is these that explain the link (Brown *et al.*, 1986; Fergusson *et al.*, 1992).

Another problem is one that plagues cross-sectional research and involves associations that arise through reverse causation. That is, where risk factors are brought about by psychopathology or its early manifestations. Many environmental experiences are shaped by individual behavior and perceptions (person–environment correlation). For example, behavior and

behavior problems in children have been shown to affect how adults deal with children even when they are unrelated, as shown in adoption studies, which we discuss later (Ge *et al.*, 1996; O'Connor *et al.*, 1998), or in experimental situations when the adults are not known to them (Anderson *et al.*, 1986). Another example relates to ADHD, which is more common in boys and known to be associated with negative mother–son relationships. While it is theoretically plausible that relationship quality plays a causal role, treatment and longitudinal studies suggest it is the features of ADHD that have contributed to the negative relationships (Schachar *et al.*, 1987; Lifford *et al.*, 2009).

Finally, it is well recognized that spurious associations can arise through confounding where a “third variable” accounts for the link between putative risk factor and outcome. Unfortunately, statistically adjusting for multiple measured confounders using, for example, multivariate methods, does not deal with this for many reasons (Rutter & Thapar, in press). Also, regardless of how well the risk factor, outcome, and confounds are assessed, unmeasured and unknown (the so-called “residual”) confounding remains an important problem.

The impossibility of ever being able to completely adjust for selection and confounding through traditional observational epidemiology, coupled with the practical and ethical impossibility of randomly allocating individuals to specific risk exposures, underpins a major motivation for making use of natural experiment and animal models. While randomized controlled trials remain the “gold standard” for testing the effectiveness of treatments and interventions, the mechanisms that mediate treatment effect are not necessarily ones that played an initial causal role.

Natural experiments take advantage of circumstances, whereby links between exposure to the risk factor and other variables are separated by naturally occurring events or situations and the manipulation involved is not undertaken by the researcher. They involve both design and statistical methods that can also be applied to existing data and ongoing studies, including population cohorts and national registries. The types of analyses that have been suggested are more sophisticated than standard multivariate statistical approaches and aim to address the problems of selection and observed and residual confounding.

Natural experiment designs used to test causal hypotheses on environmental risks and that control for genetic contribution

Twin designs

While they are not always acknowledged as such, twin designs do actually represent a natural experiment. These take advantage of the fact that monozygotic (MZ) twins, in principle, share 100% of their genes (meaning DNA sequence), whereas dizygotic (DZ) twins share on average around 50%. The critical assumptions, limitations, and further uses of twin designs are

described in greater detail in Chapter 24. The twin design essentially allows for the investigation of the extent to which variation in an observed trait (phenotype) in a given population can be explained by genetic and environmental factors. This partitioning of genetic and environmental contributions (variance) can be undertaken for measured environmental factors (e.g., parenting) as well as for psychopathology. Multivariate twin designs involve examining the association (covariation) between a measured environmental factor and outcome, and decomposing the association or covariation into genetic and environmental components. Ideally, such studies need to be longitudinal. Here, by “controlling” for the genetic contribution it becomes possible to test the extent to which nongenetic influences explain the link between the environmental measure and outcome. The strength of this type of design is that it allows us to test the extent to which observed associations between risk factor and outcome are explained by genetic “confounds.” The nongenetic contribution is sometimes referred to as “environmental mediation.” However, strictly speaking, it is not possible to distinguish whether there is genuine mediation (see Table 12.1) via environmental mechanisms or whether unmeasured nongenetic factors represent a “third variable” that contributes to both risk measure and outcome.

There is now a large number of published twin studies that have utilized this method. For example, one twin study of antisocial behavior in children (Jaffee *et al.*, 2004) found that the link with corporal punishment was mainly explained by genetic factors. This could arise, for instance, through parental responses to the child’s genetically influenced behavior. That was not observed to be the case for physical abuse, where the links were explained by “environmental mediation.” However, nevertheless, the use of corporal punishment (perhaps especially if it was severe and frequent) was associated with an environmentally mediated increased likelihood of escalation into abuse. The finding underlines the fact that the origins of a risk factor and its mode of risk mediators are not the same.

Twin studies of depression in children and adolescents (Thapar *et al.*, 1998; Silberg *et al.*, 1999) suggest that while there is a strong genetic contribution to the association between life events and depression, environmental links are still evident but vary with age and the nature of the life event. For example, the relationship between independent life events over which an individual has little control (e.g., death of significant other) and depression seems to be mainly or entirely explained by environment. There is a much stronger genetic contribution to the association of depression with dependent life events. This, in part, appears to be explained by self-selection into risk exposure by those predisposed to depression (Kendler & Gardner, 2010) and that becomes more evident from adolescence on (Silberg *et al.*, 1999; Rice *et al.*, 2003).

These studies are compatible with a causal explanation in relation to links between physical abuse and antisocial behavior. They also suggest that while there is strong association

between dependent life events and depression, the causal effects are not of the same effect size indexed by the magnitude of association.

Twin study designs, however, have many assumptions and limitations (Rutter & Thapar, *in press*). Also, the findings of bivariate twin analyses, even when applied to longitudinal data do not prove causal links. Rather, by modeling genetic contributions that can index selection and unmeasured confounding, they allow investigation of potential threats to causal inferences. This could not be achieved through observational designs that are not genetically informative.

Discordant MZ twin pairs and MZ twin pair differences

This design takes advantage of the fact that MZ twins share 100% of their genes and means that differences in their characteristics or phenotype can be attributed to nongenetic influences (including stochastic—chance—effects and measurement error). This type of design can involve testing whether MZ differences in a trait phenotype (e.g., depression symptom scores) are associated with MZ differences in exposure to an environmental factor (e.g., a quantitative measure of social adversity). An alternative configuration involves examining differences in outcome for MZ twins who are discordant for a specific categorically defined exposure (e.g., a stressful event).

In one longitudinal twin study (Caspi *et al.*, 2004), the association between independently rated measures of hostility and warmth from a recorded 5 minute speech sample from the mother while being asked about the child (expressed emotion), and later teacher-rated behavioral problems was found to be explained by environmental influences (taking into account earlier behavioral symptoms). Another example is provided by a study of MZ twin birth weight differences (Lehn *et al.*, 2007; Groen-Blokhuis *et al.*, 2011). These differences were found to be associated with later MZ differences in ADHD symptom scores, although here the causal inference is more problematic. That is because birth weight is a marker of multiple known and unknown genetic and environmental exposures during the intrauterine period.

Although these designs do control for shared genes, and thus provide some valuable insights, on their own they do not allow us to draw firm conclusions on causality for a number of reasons. The environmental factor could simply be behaving as a proxy risk factor, for example indexing some other environmental risk that impacted on one twin and not the other. Another problem is that discordant MZ twins might be considered as atypical and indeed rare for very highly heritable disorders such as ADHD and autism. These issues raise questions as to why they have been subject to different experiences and whether the risk pathways involved are different in such instances. Also we now know that MZ twins are not 100% genetically identical with respect to gene expression rather than gene sequence, for example through epigenetic differences (see Chapters 24 and 25). Nevertheless, they provide a useful and important contribution by controlling for

genetic influences that can be difficult to assess in many other designs.

Discordant DZ and sibling pairs

DZ twins and siblings share on average 50% of their genes; they are not however matched genetically in the way that MZ twins are. Thus, unlike the discordant MZ twin design, these designs can only be used to test family-level (genetic and shared environment) confounds that contribute to differences in phenotypic outcomes. Discordant twin designs cannot be used to examine prenatal exposures because measures of these would be the same for each twin. There has been especial interest in utilizing siblings who are discordant for exposure to prenatal risks.

This type of design has been used extensively to examine siblings who have been discordant for exposure to maternal cigarette smoking during pregnancy. This has enabled investigators to test the relationship between maternal smoking and offspring outcomes. For example, the study conducted by Obel & colleagues (2011) found, in common with most cohort, case control studies and meta-analyses (e.g., Langley *et al.*, 2005), a strong association between maternal smoking in pregnancy and ADHD in the overall sample (odds ratios of over 2). However, the strength of association dropped considerably (to nonsignificant levels of around 1.2) in discordant sibling pairs. That is, the sibling who had been unexposed to smoking in fetal life showed elevated levels of ADHD traits. This was not the case for lower birth weight where the relationship with exposure to cigarette smoke *in utero* remained strong.

Similar findings have been observed in relation to offspring antisocial behavior and substance misuse (D'Onofrio *et al.*, 2012a, b). The findings suggest that selection effects and early unmeasured background confounds are probably contributing to much or all of the observed association between maternal smoking in pregnancy and offspring ADHD and behavioral outcomes.

Gaysina *et al.* (2013) claimed that three independent genetically sensitive designs showed that, to the contrary, there were real prenatal effects on antisocial behavior. However, that was not the case. One of the three studies used the assisted conception design (see later) but Gaysina *et al.* excluded it because the sample was too small to be pooled with the other two studies. A second study, the Christchurch study, compared 1088 children reared by biological mothers and 36 reared by nonrelated adoptive mothers. When covariates were included, the effect of maternal smoking became nonsignificant. That left only the Early Growth and Development study of adoptees, in which birth parent data were used to assess maternal smoking and adoptive home data were used only to evaluate child rearing. The initial analysis found a significant effect ($p = 0.007$) of maternal smoking, but the design was not a balanced one, and when confounders were considered the effect of maternal smoking remained but at a reduced significance level ($p = 0.01$). The Gaysina *et al.* study provides a reminder that the issue is not yet fully resolved but the weight of evidence remains in favor

of a lack of a true causal effect on either ADHD or antisocial behavior but a true effect on birth weight.

Returning to the discordant sibling design which is useful for investigating prenatal risks, again there are assumptions and limitations. Among these, a critical issue is why are mothers behaving differently in different pregnancies? That is certainly important in relation to mothers who are able to quit in one pregnancy versus ones who continue because pregnant mothers who are heavy smokers are characterized by a background of greater psychosocial adversity (Pickett *et al.*, 2009). An additional limitation applies to utilizing DZ twin and sibling discordance to examine postnatal environmental variables. In this situation, the exposed sibling might have an influence on the unexposed sibling outcome. It is also problematic that siblings are born at different times and the risks can change over time for the family unit or at a population level. For example, characteristics of the mother such as being a teenage mother can change (Harden *et al.*, 2007) and creates a potential threat to the interpretation of findings.

Children of twins designs and its extensions

The Children of Twins (CoT) design enables inclusion of genetic contributions to cross-generational links in psychopathology (Silberg & Eaves, 2004; D'Onofrio *et al.*, 2003; see Chapter 28) and to links between parentally influenced risk factors and offspring outcomes. It utilizes the fact that the offspring of MZ and DZ twins are socially cousins but the MZ twin offspring are genetically half siblings (the DZ twins are of course genetically cousins and share around 1/8 of their genes).

For example, this type of design has been used to examine prenatal risks. One study found that in the offspring of alcoholics (Knopik *et al.*, 2006), when genetic influences were included, maternal smoking in pregnancy no longer appeared to be associated with offspring ADHD; a finding similar to that reported in the discordant sibling studies. CoT designs have also been used to examine postnatal adversity. One such study (Lynch *et al.*, 2006) found that harsh physical punishment remained associated with childhood behavioral problems when genetic factors were included, thereby showing convergence with the discordant MZ twin study findings. In an Australian study of twins, their spouses, and offspring, the aim was to assess cross-generational transmission of depression. Here, environmental factors explained the link between parent (twins) and offspring depression even when a history of depression in the spouse of the twin was taken into account (Singh *et al.*, 2011).

An extension to the CoT design (eCoT) involves integrating data from adult twins and their children with data on child twins and their parents. Such designs have also suggested a strong environmental contribution to the cross-generational transmission of depression (Silberg *et al.*, 2010). Interestingly, another investigation that utilized the extended CoT design suggested that while the link between adult antisocial personality disorder and offspring depression was environmental, the association with offspring conduct problems was explained by genetic

and environmental factors and the relationship with offspring ADHD was entirely explained by genetic factors (Silberg *et al.*, 2012).

Another variant uses longitudinal data on the adult and child twins (LTaP). Critical limitations of the first two designs include the assumptions that there are no cohort effects and the equivalence of phenotype across generations and ages. Assortative mating (nonrandom selection of partner that is correlated with genetically influenced attributes) is also an important influence that is difficult to control for using measured variables.

Nevertheless, confidence is added by findings from other designs that have different limitations. For example, the environmental contributions to cross-generational links in depression have been observed in two CoT studies (Silberg *et al.*, 2010; Singh *et al.*, 2011) and, as we describe later, an adoption study (Tully *et al.*, 2008) and using an assisted conception design (Lewis *et al.*, 2011). Like all genetically informative designs, while these studies can undertake tests that allow inclusion of genetic contributions, they cannot on their own prove causal hypotheses.

Adoption studies

Adoption studies enable separation of genetic and prenatal influences from postnatal experiences in the adoptive placement. Such studies were originally used to examine genetic contributions to disorders, but they are also an invaluable way of testing postadoption environmental influences. Rearing influences, of the type that are likely to be shaped by genetically influenced parental attributes, would ordinarily be correlated with children's psychopathology but the association could arise from noncausal genetic reasons. This is because of genes shared by parents and their offspring. The strength of adoption studies lies in the removal of this passive gene–environment correlation contribution to postnatal environmental variables, because children are being reared by “biologically independent” adoptive parents. For example, a study of adopted away children (e.g., Ge *et al.*, 1996) showed that negative parenting from the adoptive parent was environmentally linked with their adopted children's antisocial behavior. In addition, adoptive parents' behavior was also associated with their child's biological parental psychiatric problems (substance abuse/dependency or antisocial personality); this association was mainly mediated via the child's hostile/antisocial behavior. These findings are compatible with causal effects of parenting on children's antisocial behavior, and children's genetically influenced antisocial behavior in turn influencing the behaviors of unrelated adoptive parents.

One of the most attractive aspects of adoption designs is that they also allow for testing gene–environment interaction (see Chapter 24); that is, testing whether environmental influences modify the manifestations of genetic liability. For example, one early study found that children who were genetically predisposed to lower cognitive ability (indexed via data on the biological parent) and were reared in more socially advantaged adoptive families showed greater rises in IQ than those reared

in adoptive families of lower social class (Duyme *et al.*, 1999). Another investigation of adoptees identified from national Swedish longitudinal registry data focused on those whose biological parents had died or were hospitalized as a result of suicidal behavior (Wilcox *et al.*, 2012). This alone did not increase risk for adoptee suicidal attempts and neither did exposure to the adoptive mother having a history of psychiatric hospitalization when the adoptee was younger than 18 years. However, the authors reported that in those at genetic risk, exposure to psychiatric hospitalization of the adoptive mother during childhood amplified the risk for a suicidal attempt.

Adoption studies demonstrate the importance of the rearing environment even in those genetically predisposed to developing problems. There are, however, a number of limitations and assumptions to the adoption study design. First, adoption is an unusual and now rare event in many countries. Children who are adopted away are likely to have been exposed to prenatal adversity and carry more risky genes. Thus, while suited to examining contributions of the rearing environment, they are not useful for examining prenatal risks. That is because adoption designs, unlike some of the genetically sensitive designs cannot separate the effects of genes and maternally influenced prenatal environment on offspring satisfactorily as **both** are provided by the biological mother. Another difficulty is that adoptive families tend to be from more advantaged groups, thereby restricting the range of environmental risks and lowering power to detect important risk effects (Stoolmiller, 1999), although as yet that has not been found to be a serious threat. Further, it assumes the absence of selective placement. The timing of adoption is also important. If adoption occurs at birth, that removes the possibility of biologically provided postnatal factors contributing, but this has not always been possible.

Despite these caveats, the adoption strategy provides a very useful means of controlling for genetic factors when examining post adoption environmental influences.

Assisted reproductive technologies

Another design is based on children who have been conceived through assisted reproductive technologies (ART; Thapar *et al.*, 2007). This is especially helpful for separating genetic and intrauterine influences as that cannot be done in twin or adoption studies, although it can also be used for other purposes. Children born through ART differ in the degree of genetic relatedness to the mother. If association between a prenatal factor and outcome is environmentally linked, then the association should be observed regardless of whether the child is genetically related to the woman undergoing the pregnancy (homologous *in vitro* fertilization, sperm donation) or unrelated (egg or embryo donation). This design has been used to investigate associations between maternal smoking in pregnancy and trait measures of ADHD and antisocial behavior (Thapar *et al.*, 2009; Rice *et al.*, 2009). In keeping with previous studies including a meta-analysis undertaken by the authors (Langley *et al.*,

2005), in the total sample, maternal smoking in pregnancy was strongly associated with ADHD and antisocial behavior. However, the association was only observed in genetically related mother–child dyads, suggesting that the contribution of unmeasured genetic confounds accounts for all or much of the association. The sample size was very small, but nevertheless it is interesting that the pattern of findings was different for lower birth weight, in which the results confirmed what was already known about the hazards of smoking during pregnancy. Also, as observed in the discordant sibling studies, including measured confounders was not a substitute for design features.

Investigations of cross-generational transmission and postnatal factors have also been undertaken in this design, as it allows some control (one parent will still be genetically related) of parental genetic factors (passive gene–environment correlation). Using this design, significant environmental links have been observed between maternal and offspring depression (Lewis *et al.*, 2011) and between hostile parenting and offspring antisocial behavior (Harold *et al.*, 2012). There are, however, a number of limitations and assumptions of this design. These include the representativeness of families who have undergone ART treatment, the low prevalence of risks (such as maternal smoking in pregnancy), and the types of measures that have been feasible so far (parent reports and antenatal records). It is of note, however, that there is convergence of findings across different designs in relation to the environmental contribution to cross-generational links in depression as already discussed (Tully *et al.*, 2008; Silberg *et al.*, 2010; Lewis *et al.*, 2011; Singh *et al.*, 2011). The findings on maternal smoking in pregnancy and ADHD and antisocial behavior are also in keeping with those from CoT and discordant sibling studies.

Maternal versus paternal exposure during pregnancy

Another method that has been used to disaggregate intrauterine and genetic or household-level influences is based on examining associations between maternal and paternal exposures during pregnancy and offspring outcomes. Here, if the link between exposure and offspring outcome is via intrauterine effects, a stronger association would be expected in relation to maternal exposure. For example, in a UK population cohort, strong associations have been observed between maternal smoking in pregnancy and shorter birth length (Howe *et al.* 2012) and lower birth weight in offspring (Langley *et al.*, 2012) that were not apparent when exposure to paternal smoking was assessed. However in the same cohort, associations between exposure to smoking in pregnancy and ADHD were as strong for maternal exposures as for fathers, even when paternal smoking was examined in the absence of maternal smoking and the contribution of additional passive smoking was considered (Langley *et al.*, 2012). Limitations of this design include the fact that it can only deal with exposures of the sort that both parents could experience in pregnancy and parents are likely to show

similarities in exposures for genetic (assortative mating) as well as social reasons.

Migration

A very different type of strategy utilizes migration. This has been used to test the contribution of environmental factors while holding group-level genetic ones constant. This design essentially involves investigating rates of disorder in one ethnic group that has migrated to a country with a very different set of environmental exposures and comparing them with rates of disorder in the nonmigrated group based in the country of origin and with nonmigrants in the host country. The best known example here relates to the rate of ischemic heart disease in Japanese who migrated to the United States and became exposed to marked lifestyle changes, for example involving diet. Rates of heart disease rose to levels that were much higher than found in Japan, the country of origin and similar to those found in the host country, that is, the United States. These findings highlighted the important contribution of nongenetic lifestyle factors to ischemic heart disease.

In psychiatry, the best known example is the observed higher prevalence of schizophrenia in migrants of Afro Caribbean origin to the UK and Netherlands (Jones & Fung, 2005; Coid *et al.*, 2008) when compared with the rates of disorder in the Caribbean and among nonmigrants in the host countries. The possibility of the process of migration itself being a key stressor is offset here by the observation that an increased rate was also observed in the subsequent generation. It is not yet known what the key causal environmental risk factors are.

While migration strategies have provided some useful information, there are also important limitations and assumptions. These include potential selection effects in the groups that migrate. Heterogeneous social, economic, and political “push” and “pull” factors lead to migration of some groups and there are potential advantages as well as disadvantages of migration (e.g., better access to health care and educational opportunities in the host country as well as social stresses).

Natural experiment designs that aim to remove or reduce selection or allocation bias in defined populations

We have highlighted that a key challenge to identifying causal environmental influences is that there are important selection and allocation biases including genetic influences that affect exposure. A number of studies have utilized naturally occurring situations whereby risks have been introduced to or removed from an entire population, thereby minimizing such biases.

Universal introduction of risk

Two well-known studies examined the consequences of intrauterine exposure to famine. The 1944–1995 Dutch Hunger Winter (Stein *et al.*, 1975) and the 1959–1961 Chinese

famine (St Clair *et al.*, 2005) resulted in essentially universal, time-limited exposure to famine that for some fell around the time of conception or early gestation. Exposed offspring showed around a twofold risk of schizophrenia as well as congenital anomalies of the central nervous system (McClellan *et al.*, 2006). Additional investigation based on imaging a small subsample suggested that those exposed to famine including those with schizophrenia also showed brain abnormalities (Hulshoff Pol *et al.*, 2000). These findings suggest that the observation of elevated rates of schizophrenia is biologically plausible.

Furthermore, in the Dutch study, exposure to famine was found to be associated with later epigenetic dysregulation (Heijmans *et al.*, 2008). A follow-up of those exposed to famine during the Dutch Hunger Winter six decades later found less DNA methylation of the imprinted gene, insulin-like growth factor 2 (*IGF2*), when compared with their same-sex siblings (Heijmans *et al.*, 2008; Tobi *et al.*, 2012). This gene codes for a hormone that plays a major role in fetal growth. The association was specific for periconception exposure. As there was no evidence of selection for risk exposure in both of these famine studies, the findings suggest that extreme prenatal nutritional deficiency in early pregnancy is likely a causal risk factor for schizophrenia. However, whether this has relevance beyond these extreme circumstances is unknown. The findings on brain alterations and the contribution of early life environmental exposures to long-lasting epigenetic changes are intriguing. They also could provide some clues about possible risk mechanisms, although, of course, the exact nature of these requires much more investigation.

Universal removal of risk

The strength of this design is that it removes the influence of personal choice that is a major confound in most observational studies. In one particularly interesting longitudinal epidemiological study of over 1000 children, the investigators took advantage of a naturally occurring situation that arose during the study. This enabled the investigators to examine the effects of family relief from poverty on child mental health (Costello *et al.*, 2003). A quarter of the original study sample consisted of American Indians and halfway through the study, a casino opened on the reserve. This provided a substantial increase to the family income of American Indians that increased every year. Data on child mental health were available before this event and after. The researchers were able to show that the relief of poverty resulted in a decrease in levels of oppositional defiant disorder and conduct disorder. As there was no selection, the findings were consistent with causal effects. The benefits appeared to be mediated via altered parenting that included the provision of increased parental time and supervision. Interestingly, levels of adolescent depression and anxiety were not altered. Further follow-up into early adulthood showed that the family income supplementation provided in childhood continued to be associated with lower rates of total psychopathology, notably alcohol and cannabis abuse and lower rates of convictions for minor

offenses and higher levels of education. There were no links with later nicotine or other drug use, emotional or behavioral disorders (Costello *et al.*, 2010).

Interrupted time series

The interrupted time series design takes advantage of multiple waves of data observation that occur before and after the introduction (or removal) of the putative causal variable, the timing of which is known. This is sometimes used to examine the effects of policy or treatment; for example, the observed drop in deaths from paracetamol overdoses after the introduction of UK legislation to reduce paracetamol package sizes (Hawton *et al.*, 2013). However, this type of design can also take advantage of naturally occurring events and be used to test etiological hypotheses.

One example is provided by investigations of gang membership in relation to delinquent activities. Gang membership is known to be associated with higher rates of delinquency, but it is difficult to know whether this is due to selection effects; that is, whether the observed association is explained by attributes of those who join gangs or arises through the social effects of being in a gang. An early study (Thornberry *et al.*, 1993) contrasted levels of delinquency across different time periods; before boys became gang members against during the time they joined and after they left the gang. Later studies (Thornberry *et al.*, 2003) extended the approach by using more sophisticated analytic approaches to further consider possible biases and retrospectively to examine gang membership prior to the onset of the study. The findings suggested, as might be expected, important selection effects. Boys who joined gangs were more delinquent than those who did not. However, they also showed that gang membership had additional social influences because rates of delinquency dropped once boys left the gang, although not back to the level that they were prior to joining a gang. In this example, it is difficult to rule out reverse causation effects whereby the decision to leave a gang is influenced by a drop in its delinquent activities or to completely rule out a contribution of unmeasured confounders. Also, the designs did not allow for testing the mechanisms by which gangs might have had this effect.

Using changes in policy as natural experiments

China's one child policy

Another quasi-experimental design was provided by China's "one child policy" (Cameron *et al.* 2013) that again was applied to a large population and the timing was known. This allowed a test of the psychological effects of being an only child. In other contexts, being an only child is confounded with multiple factors that influence the decision or likelihood of having only one child, that is, selection or allocation effects. The authors examined children born prior to the introduction of the one child policy in 1979 and compared them to those born after that policy from the same area. They utilized questionnaire

measures of personality traits and experimental data generated from standard economic games that were designed to assess altruism, ability to trust others and trustworthiness, risk taking, and competition. This study, based on 421 children, showed that the policy, which behaved as an instrumental variable for being an only child (see later), resulted in individuals who were more pessimistic, more risk averse, less conscientious, less competitive, and less prosocial. The imposed policy meant removal of the usual sorts of selection effects that would be operating and the study dealt effectively with the range of methodological matters needing attention.

Change in legislation on sale of alcohol in Sweden

A different type of study focused on the effects of prenatal alcohol exposure in two regions in Sweden that were exposed to an experimental policy change in the sales of alcohol. The intention had been to shift the population from drinking spirits to drinks with lower alcohol content. However, the policy inadvertently resulted in very marked increases in the consumption of strong beer during a very specific time period. This was especially the case among teenagers due to age restrictions for the purchase of other types of alcohol (Nilsson, 2008). The experimental policy started in 1967 but was terminated abruptly in mid 1968 when it was realized that it had led to a very sharp increase in alcohol consumption. As the experiment was time-limited, it provided the opportunity of comparing the cohort who were *in utero* during this time period to those in adjacent time-unexposed cohorts. As it was geographically restricted, it also provided the opportunity for comparisons of children born in the same cohort from the exposed and unexposed regions. Using Swedish national registry data, it was found that the exposed group who had been *in utero* during the experimental period and were around 30 years, showed greatly reduced educational achievements, lower earnings, and greater welfare dependency than the comparison cohorts. The effects were strongest in males, those exposed for the longest in intrauterine life, and those born to younger mothers. The magnitude, timing, and geographical distribution of the effects suggested that prenatal exposure to alcohol likely had long-lasting consequences on offspring, although the mediating mechanisms are not known. Another problem is that the results are derived from analyses at a group level and there is thus uncertainty about effects on individuals. Nevertheless, this study illustrates how policy changes can provide an opportunity for natural experiments in whole populations, whereby the threats of reverse causation are removed and the problems of selection and contribution of confounders diminished. There are also, however, limitations and assumptions of these types of studies. For example, they rely on inferences rather than direct measures. It is impossible to rule out the contribution of other confounders that operate, for example, postnatally and it is not known how generalizable findings would be outside the quasi-experimental situation.

Radical changes in environment

Adoption following profound institutional deprivation

Another example of a natural experiment that involved change of a different type and that was radical is provided by the English and Romanian Adoptees study (Rutter & Sonuga-Barke, 2010). This involved a longitudinal follow-up investigation of children who were exposed to institutional care from the time of early infancy and extreme deprivation. Many critical selection biases were absent because the children were admitted very early before they may have had an influence on their admission into care, thereby reducing the possibility of reverse causation. Virtually no children left care until the government regime fell in 1989, thereby also removing the possibility of selection as to which children remained in care. These children subsequently experienced a dramatic change in environment after they were adopted into relatively advantaged families in the UK. A natural experiment design was further facilitated by accurate timing of children's removal from this context. The study suggested that institutional care of the type experienced by these children had possible causal effects because there was considerable and major recovery of deficits following removal from that context. The design could not distinguish deprivation effects from benefits attributable to the adoptive home. Nevertheless, variations within the adoptive home environment did not seem to contribute to differences in outcome in the age 15 group. Many tests of alternative explanations were undertaken and, as highlighted at the start of this chapter, this is critical. Overall, these suggested that a causal inference is justified despite some limitations, such as an absence of data on biological parents and the question of the extent to which findings might apply to less severe and more common forms of deprivation. As was the case for the famine studies, sometimes natural experiments have involved extreme and less common forms of environmental risk, thereby raising the issue of generalizability to more typical contexts.

Regression discontinuity

Regression discontinuity (RD) designs were originally put forward as an alternative to randomized controlled trials. They take advantage of situations where an intervention is provided to those who fall beyond a strict cut-point on a specific measure (e.g., level of poverty), rather than where allocation is through randomization. The selection bias here is utilized because it is imposed externally, the bias cannot be caused by the intervention or in nonexperimental settings, the "causal risk."

The slope of a regression line as visualized graphically represents the strength of association between a predictor (e.g., poverty level) and an outcome (e.g., cognition and behavior). Where there is discontinuity in the regression at the cut-point for selection, it suggests a causal effect of intervention on outcome.

This type of design has been used for assessing the effects of experimental interventions, but there is little on its use in relation to testing nonexperimental causal risks. For example,

an RD design was used to examine the effects of Head Start, a program for preschool health and social services to poor children aged 3 or 4 years in the United States (Ludwig & Miller, 2005). In 1965, assistance was given to the 300 poorest counties, which led to very marked higher levels of funding and participation in these counties. The RD design involved comparing those just above the cut-point and those just below the cut-point for this assistance. The findings suggested a substantial impact of Head Start on health measures and school graduation but not on noncognitive outcomes. The inference of likely causal effects was strengthened by finding that similar effects were not found in age groups that were unexposed to Head Start or to health outcomes that were not plausibly related to the impact of Head Start. Nevertheless, there are many limitations including a lack of accurate individual level data on exposure (e.g., effects of families moving in and out).

Another example is provided by a study that set out to examine whether cognitive performance in school children was affected by the amount of schooling received versus being older in chronological age (Cahan & Cohen, 1989). This was enabled by a system whereby all children in state-controlled Hebrew language primary/elementary mainstream schools in 1987 were admitted at one time point in December. The authors excluded any children who were under- or over-age in each of the classes studied and those born in November or December. Thus, children at the end of one school year and the beginning of the next would have a one-year difference in schooling received. In any given class, the youngest and oldest would have received the same amount of schooling but differ much more in chronological age. This study showed that the amount of schooling contributed more than older age to nearly all the cognitive measures used.

Using instrumental variables

An instrumental variable is a measured variable that is associated with the predictor (risk factor) being tested but that is not subject to the same social selection effects and confounds including shared genetic influences. Instrumental variables are used as a statistical method to deal with unmeasured confounding in observational and treatment studies, but there are also situations when they can be used as a basis for a natural experiment.

Early puberty provides an example of an instrumental variable in relation to early use and misuse of alcohol. These are behaviors that have been considered as possible causal risks for later alcohol dependence and misuse in adult life. Early puberty is strongly associated with early alcohol use and misuse but is a variable that is not subject to the same selection effects. Three studies find that while early alcohol use and misuse in adolescence is associated with later alcohol related problems, early puberty does not predict adult alcohol problems (Stattin & Magnusson 1990; Caspi & Moffitt, 1991; Pulkkinen *et al.*, 2006). These findings suggest that early alcohol use, rather than being a cause of later alcohol problems, is likely an early manifestation of the same liability.

Mendelian randomization

Mendelian randomization (MR) is a variant of the instrumental variable approach. This method has been proposed to provide another means of testing causal effects when unmeasured confounding is a likely problem. Here, a genotype is used as the instrumental variable for the risk factor in question. It utilizes the fact that there is random assortment of parental genotypes at meiosis and thus, theoretically, genotypes are not subject to the same confounds as the risk factor under consideration. It has perhaps been most successfully used in the realm of cardiovascular disease. For example, MR has recently been used to evaluate the causal risk effects of cholesterol levels on myocardial infarction ("heart attack"). In a very large study (Voight *et al.*, 2012) that utilized two genetic instrumental variables (a composite genetic score and a loss-of-function coding gene variant), the authors found evidence to suggest that increased HDL cholesterol (which is considered the "good type" of cholesterol) does not lower the risk of myocardial infarction. The results suggested that attempts through treatment to increase levels of what has been called a "good" type of cholesterol are not supported. However, there are a number of assumptions of the MR design (e.g., pleiotropy, whereby genes have multiple different effects) that we discuss later.

Another study used risk scores from gene variants in alcohol metabolizing genes as a genetic instrumental variable in a UK birth cohort of several thousand children (Lewis *et al.*, 2012). The authors found that these gene variants were related to lower IQ at age 8 but only in the offspring of mothers who were moderate drinkers of alcohol during pregnancy, not those whose mothers abstained from alcohol.

While an elegant design, there are a number of critical assumptions that require systematic evaluation when MR is applied (Glymour *et al.*, 2012), some of which are especially problematic in relation to mental health phenotypes. For example, there is a need for genetic variants that have a strong and robust association with the risk factor in question. If the genotype (instrument) has pleiotropic effects and has multiple effects on different phenotypes, which seems common in relation to mental health (see Chapter 24), or influences another intermediate phenotype, this creates problems. If that intermediate phenotype affects the clinical outcome or influences a confounding factor, key assumptions are violated.

Statistical methods to reduce selection biases and confounders

We do not provide a detailed description of statistical methods but rather flag up that there are many such analytic techniques. These methods attempt to address selection differences between groups exposed and unexposed to the risk factor in question and take into account measured confounders. While these have been useful developments, because they allow for less biased estimates of association, residual confounding remains a

problem. Propensity scores can be used for statistical matching of the group exposed to the risk factor in question (or intervention) to the one that is unexposed. It utilizes the covariates that predict exposure to the risk (or receipt of intervention) that will include variables that preceded the exposure. Thus, it requires observed, measured predictors typically derived from regression analyses and is still limited by the problem of residual confounding and selection effects that are not captured by measured predictors. Inverse probability to treatment weighting involves using propensity scores as weights to create more representative samples (Rutter & Thapar, in press).

A propensity score matching method was used by Kendler and colleagues (2010) to test the likely causal effects of dependent life events on major depression and was strengthened by combining it with a design involving MZ twins who were discordant for exposure to dependent life events. They found a substantial proportion of the association appeared to be due to noncausal effects, but the complementary designs were consistent with life events having a modest causal risk effect.

Other analytic approaches involve statistical modeling that utilizes data from multiple data points. These include structural equation modeling (SEM) and latent growth curve modeling. Where multiple measures and ideally longitudinal data are available, SEM allows for simultaneously testing relationships between hypothesized risk and outcome variables across and within time and for incorporating measured confounders of risk exposure into the statistical model. Latent growth curve modeling requires repeated observations of the same data over time. It moves beyond group-level analyses and allows testing for individual-level change as a function of time. Risk exposures during a certain time can be examined in relation to alterations in growth curves. These methods can also be used to test potential mediating mechanisms. These, however, are statistical methods rather than designs. They rely on *a priori* specification of the causal model and infer causal links by assessing fit of the model according to statistical criteria and the use of measured confounders. Explanatory models and mediating mechanisms that are statistically satisfactory are not necessarily correct. They provide a platform from which to test alternative explanations ideally through different designs.

Experimental manipulation in humans

As a bridge between natural experiments and animal models, it is appropriate to mention the use of human experiments, for example, assessing hyperventilation and anxious behavior in response to a carbon dioxide challenge, because the same strategy may be able to be used in animals as well as humans (Battaglia *et al.*, 2014). Their uses in studying gene–environment interaction by examining how individuals respond to stimuli in an experimental situation are considered in Chapter 23. For example, the use of an experimental induction of emotion showed how a specific genotype (5HTT transporter gene

variant) altered an intermediate brain imaging phenotype in response to the emotional stimulus, with the brain functional changes lying on the same biological pathway as that leading to psychiatric disorder.

Animal models to test environmental influences

Most of the best animal models dealing with environmental effects that are relevant to clinical practice had their origins in clinical observations or theories that were supposed to deal with the clinical features. For example, the Nobel prize winning work by Hubel and Wiesel examining the effects of binocular visual input to the growth of the visual cortex was prompted in part by the observations of Von Senden (1960) that children with congenital cataracts have substantial, and often permanent, visual deficits after removal of the cataracts. Riesen's research with animals provided similar observations (Riesen, 1961). Hubel and Wiesel undertook various experimental manipulations but the one that is prototypical is the suturing of the eyelids of one eye in order to determine the effects on the brain. In keeping with the best of animal models, they examined the possibility that the cortical effects were related more to competition between the eyes than to simple disuse (finding that they were). Also, they went on to examine in much more detail the changes in the visual cortex (Hubel & Wiesel, 2005). In short, the basic science findings in the animal model led on to further studies of what was happening in the brain. The findings from the animal model were important also in indicating the need to intervene early in life to deal with strabismus in young children.

Somewhat similar lessons derive from the research by Rosenzweig and Bennett and their colleagues (Rosenzweig *et al.*, 1962). Their starting point was the observation that laboratory rats that were given formal problem-solving training had neurochemical changes in the cerebral cortex. This led on to experimental studies of deprivation and enrichment. In brief, rats reared in single cages (deprived conditions) were compared with those reared in a large cage containing 10–12 animals, with a variety of stimulus objects that was changed daily (enriched conditions) (see Chapter 23). In the early experiments, the study was done on juvenile animals on the grounds that the effects should only be found at a time of maximal brain growth. Later studies compared juveniles and adults, with the striking finding that effects were broadly similar in adults as in juveniles, although the effects were greater in the young (Rosenzweig & Bennett, 1996). In line with later human studies, it was evident that adult experiences could change brain structure (see Chapter 23).

The work of Levine, undertaken at much the same time, had its basis in Freud's theory that early life stress contributed to the development of subsequent emotional instability. Contrary to expectation, Levine *et al.* (1956) found that rats exposed to intermittent foot shocks actually had a diminished susceptibility to

later stress and this exposure also affected the neuroendocrine system (Levine, 1957, 1962). It was typical of a good use of an animal model that the failure to confirm the original expectation led on to further exploration of the “steeling” (strengthening) effect. Thirty years later, Lyons and colleagues, working in the laboratory that Levine founded, began to investigate the long-term effects of brief, intermittent mother–infant separations in squirrel monkeys (Lyons *et al.*, 2010). Socially housed squirrel monkeys were randomized to either brief intermittent separations or a nonseparated control condition at 17 weeks of age. For each of the separations, one monkey was removed from the rearing group for a one-hour session. The aim was to determine whether the intermittent separations (which were designed to mimic those that normally occurred in the wild) provided a form of stress inoculation that enhanced arousal regulation and resilience (Lyons *et al.*, 2009). The findings showed both diminution in anxiety and increased exploration of novel situations but also biological effects in the neuroendocrine system and the brain. In conjunction with other findings, it has been concluded that exposure to challenge and manageable stress can enhance resilience in humans (Rutter, 2013).

Harlow’s classic experimental studies with rhesus monkeys showed the profound effects of social isolation. The original motivation for the studies lay in the human studies (such as those by Goldfarb), but Harlow was also influenced by what he saw as the narrowness of classical conditioning such as undertaken by Skinner. His aim was to test the extent to which loving contact was shaped only by the reward of food. The experimental design involved the so-called “cloth” and “wire” mothers, each of which could be made to provide, or not provide, nourishment. The findings were clear cut in showing that the babies sought the comfort of contact irrespective of feeding (Harlow, 1958, 1963). Not only were there immediate differences in behavior but social isolation was also found to have long-lasting effects (Harlow & Suomi, 1971) that were quite difficult to reverse completely (Novak & Harlow, 1975). Harlow’s research made a huge impact on the field and the findings were taken up by Bowlby in his writings on attachment. However, the studies dealt with quite extreme conditions and the later studies by Harlow have been generally regarded as unnecessarily cruel and ethically unacceptable (Blum, 2002).

Hinde’s research, also dealing with rhesus macaque monkeys, was quite different in focusing on a more normal range of situations and in concentrating on the influences on individual differences (Hinde & Spencer-Booth, 1970; Hinde & McGinnis, 1977). Three main findings were particularly important with respect to human implications. First, they found that the infant’s distress following separation was a function of both the pre-separation and contemporaneous mother–infant relationship. Second, changes in the mother–infant interaction largely depended on the mother and, third, the infant showed much less post separation distress and more normal mother–infant interaction when they themselves were removed to a strange place for 13 days and then restored to their mother than when

the mothers were removed to a strange place for a similar period. Hinde has argued convincingly that post separation distress was more a consequence of disturbance in maternal behavior than in the direct effects of the separation itself. These studies are a model of careful, rigorous comparisons that were well designed to test hypotheses, of great potential relevance for humans. The work of Harlow and Hinde are good examples of what can be achieved by animal models and it is important to note that a far wider range of investigators dealt with similar issues (Rutter, 1981; Blum, 2002).

Harlow and Suomi (1974) worked together to develop peer-rearing as an important risk experience for later development. For over a dozen years now, Suomi has run a randomized controlled trial contrasting mother-reared rhesus monkeys, peer-reared rhesus monkeys, and surrogate-peer-reared rhesus monkeys (Conti *et al.*, 2012). Numerous studies have consistently shown the detrimental long-term effects on health associated with peer rearing. The use of animal models by Suomi’s group has provided major advances in two respects. First, experimental conditions are randomly allocated (which, perhaps surprisingly, has not been true of many animal models); and, secondly, the outcomes have been examined, not only with respect to cerebrospinal fluid differences during life but also epigenetic findings using postmortem hippocampal tissue. The results were used, amongst other things, to examine gene \times environment interactions ($G \times E$) (Lindell *et al.*, 2012). It was found that differential rearing led to differential DNA methylation in both prefrontal cortex and T cells (Provençal *et al.*, 2012). The finding that early life social adversity was associated with modulation of the developing immune system provides confirmation of the human evidence on the same topic (Danese *et al.*, 2008; Danese *et al.*, 2011).

The next example of an animal model concerns Meaney’s program of research into the epigenetic effects of the environment on gene expression (see Chapter 25) that represents quite a different form of investigation. Rather than aiming to provide any kind of parallel to human rearing, it sought to examine a mechanism that was likely to operate across species. The research began with the observation that lactating mother rats varied markedly in the extent to which they licked and groomed their offspring and showed associated arch-back nursing (both being *unassociated* with the amount of maternal time spent with the pups). These individual differences were associated with neurochemical variations in a particular brain region, as well as individual differences in the pups’ behavior and response to stress. A cross-fostering design was used to determine whether the effects were due to biological inheritance or rearing environment—with the findings supporting an effect of rearing. It was then shown that the maternal behavior had altered the endocrine response to stress lastingly via an effect on a specific glucocorticoid receptor gene promoter in the hippocampus. The next question was whether the epigenetic effects could be reversed by using a particular drug to reverse the methylation effect. It was found that reversal could be brought

about—providing further confirmation of a causal effect. These initial findings are interesting and important. As ever, replication and further investigations will be needed as complex multifactorial phenotypes such as altered stress response will likely involve different types of epigenetic changes across multiple genomic sites and the rearing environment could also impact on other types of biological mediating mechanisms. Nevertheless, it is no exaggeration to state that the findings from these ingenious, well-controlled experimental studies led to a paradigm shift in the understanding of environmental effects on gene expression.

Fernald and Maruska (2012) also studied epigenetic effects of environmental influences, but did so in relation to experimentally induced changes in social dominance in zebra fish. They first showed that males can rapidly and reversibly switch between dominant and subordinate status, this being accompanied by a dramatic change in body coloration and changes in gene expression in the preoptic area of the brain. They found that visual cues of social encounters were crucial. Two dominant males, differing in size by a factor of 4, were allowed to establish territories out of view of one another because of an opaque barrier. When that was replaced by a transparent barrier, the smaller male suppressed all dominant behavior. Through manipulation of this situation, Fernald and his colleagues were able to induce either a rise or fall in social rank with consequences for gene expression. While the social worlds of zebra fish and humans are very different, social rank is a ubiquitous element in all social systems and an essential organizing principle in understanding social behavior. The experimental control in this animal model provides a good test of causation, with epigenetic findings that are likely to apply widely across species, including humans.

Animal models have also been used to examine the effects of physical toxins and perinatal adversity; most notably, they have been helpful in the study of the effects on the fetus of mother's alcohol consumption during the pregnancy. Once more, the animal models start from a human observation, namely, the identification of the congenital anomalies associated with high levels of alcohol exposure during the first trimester of pregnancy (Jones *et al.*, 1973). Animal studies were informative in showing the same congenital anomaly effects as in humans but were mainly of value in tackling the question as to whether low levels of alcohol exposure might have similar, albeit lesser, effects (Cudd, 2005). This question was important because of the limited relevant data from human studies (see Gray & Henderson, 2006). To date, there have been a rather limited number of studies, using both rats and rhesus monkeys, but these suggest that there may be greater effects from low to moderate levels of alcohol exposure during the pregnancy than had hitherto been supposed (see Gray *et al.*, 2009). Similar approaches have been used to study cigarette and nicotine exposure *in utero* in rats. The findings have shown a consistent effect, leading to a lower birth weight but not the motor and cognitive changes that might form a parallel with ADHD (LeSage *et al.*, 2006; Winzer-Serhan, 2007). Animal

experimental models have also been used to examine the effects of exposure to perinatal hypoxia. For example, rodents exposed to chronic perinatal hypoxia show cognitive deficits that appear to be related to specific brain and cellular anomalies and that some of these deficits may be ameliorated by environmental enrichment (Vacarino *et al.*, 2013; Salmaso *et al.*, 2014).

Animal models to study the causal effects of genetic risks

In principle, genetic influences raise the same need for testing of causal inferences. However, at first sight that might seem redundant in the case of diseases due to a single, highly penetrant, mutant gene, such as is the case with Rett syndrome (see, e.g., Zoghbi & Bear, 2012). However, that assumption would be a mistake for three separate reasons. First, the identification of the mutant gene in itself does not identify the causal pathway(s) involved. That was also the case with environmental influences (see discussion of the animal models used by Hinde and by Harlow). Second, there may be more than one mutant gene; for example, tuberous sclerosis is caused by mutation in two distinct genes. Third, often the syndromes involve several rather different features. That is the case, for example, with the fragile X syndrome. Here, we illustrate what may be achieved with animal models of genetic risks by considering Rett syndrome, fragile X, and tuberous sclerosis. In each case, the animal model is created by some variety of engineered deletions of a specific gene or knock-in of a foreign gene. In other words, the aim is *not* to mimic the features of a specific human syndrome but, rather, to directly create an animal with the same relevant mutant gene.

Rett syndrome

Girls with Rett syndrome appear to develop normally up to about 6–18 months but head growth then decelerates leading to microcephaly (Rutter & Thapar, 2014). The children lose purposeful use of their hands and develop stereotypical hand washing movements. Epileptic seizures often start about the age of 4 years but tend to decrease in severity in adult life at a time when there is progressive neurological deterioration. Mutations in the X-linked gene encoding the methyl-CpG-binding protein 2 (MeCP2) have been found to be causal.

Mice lacking functional MeCP2 were created by Chen *et al.* (2001) and by Guy *et al.* (2001). There were two surprises in the findings. First, the mutant mice showed a remarkable degree of similarity with the human condition in both course of development (with an initial period of apparently normal development) and behavioral features. Second, despite the devastating neurological features, the brain appeared relatively normal apart from microcephaly, and a decrease in dendritic spine density (see Dani *et al.*, 2005). Thus, what had previously been regarded as a progressive neurodegenerative disorder seemed to involve a disruption of neural networks, but not

their destruction (Belichenko *et al.*, 2009). It was found that, at least in the mutant mice, gene reversal led to a reversal of the phenotype (Giacometti *et al.*, 2007; Guy *et al.*, 2007; Tropea *et al.*, 2009). Commentators have generally described this as a reversal of a neurodegenerative disorder but, in our view (Rutter & Thapar, 2014) the relatively normal brain findings combined with reversal or partial reversal suggests instead that the syndrome derives from postnatal malfunction. It remains to be determined whether the same applies in humans, but what is clear is that the genetically based animal model has led to a major rethink on the underlying biology and the causal risk effects of this gene mutation.

Fragile X

The fragile X anomaly was first reported by Lubs (1969), and it was found to be associated with many physical features (such as large testes and large low-set ears), as well as the behavioral features of cognitive impairment, hyperactivity, social anxiety, and autistic-like features. Postmortem studies in humans showed structural abnormalities of the dendritic spines. Fu *et al.* (1991) and Verkerk *et al.* (1991) showed that expansions in the fragile X gene (*Fmr1*) caused the syndrome. This evidence provided the means to produce an *Fmr1* knock-out (KO) mouse (Bakker *et al.*, 1994) that has been used in much subsequent research (Dölen *et al.*, 2007) and the suggestion that unchecked mGluR5 activation might contribute significantly to pathogenesis. *Fmr1* KO mice showed phenotypes similar to the human condition with hyperactivity, repetitive behavior, and seizures. Dolan *et al.* (2013) used the small molecule PAK inhibitor (FRAX486) to determine whether it could rescue the phenotype. They showed that it both reversed the dendritic spine abnormalities and the behavioral features of hyperactivity and repetitive movement, but it did not impact macroorchidism. Moreover, the reversals were obtained in adult mice as well as in juveniles. Again, the mutant mouse model provided an important lead on the possibility of clinical benefits in humans.

Tuberous sclerosis (TS)

TS is a neurocutaneous, autosomal dominantly inherited multi-system disorder characterized by benign tumors (hamartomas) that occur in many organs including the brain. Because of the gross brain abnormalities it is exceedingly unlikely that reversal could be brought about. Nevertheless, mutant gene rodent models have been produced. It has been found that the immune-suppressive drug rapamycin affects some changes in some phenotypes (see Tsai *et al.*, 2012). In that connection it is relevant that substantial brain dysfunction occurs independently of gross structural brain abnormalities (as in hamartomas) and epilepsy (de Vries, 2010). The mutant mouse model in this instance did not succeed in bringing about a major reversal of the neurodegenerative changes but it did lead to a broadening of the concept of the possible pathophysiological changes that might be involved as a result of specific risk genes and this might ultimately lead to clinical benefits.

These few examples do not cover the long list of mutant models that have been put forward (Robertson & Feng, 2011). Also, it is important to note that even the ones that have not led to major breakthroughs have sometimes helped in drawing attention to processes that had not been previously recognized in the human work. Bowles *et al.*'s (2012) thoughtful review of gene expression and behavior in mouse models of Huntington's disease provides a good example. Also, mice do not constitute the only source of mutant models (see, e.g., Golzio *et al.* (2012) on the use of both mice and zebra fish in relation to the role of copy number variations in producing a microcephaly phenotype).

Behavior-based animal models to study causal risks in relation to multifactorial psychiatric disorders

There is a long history of producing animal models based on behavioral similarities to some human disorder of interest. For example, a mouse model of depression has been produced by separation experiences, by forcing the mouse to swim until exhausted, by hanging the mouse upside down by its tail, and many other sources of stress (Cryan & Mombereau, 2004; Cryan & Holmes, 2005; Cryan & Slattery, 2007). The approach follows the recognition that stress and adverse experiences play a substantial role in the genesis of anxiety and depressive disorder in humans (Heim & Nemeroff, 1999). However, depression also involves cognitions such as despair, hopelessness, and self-blame that would be tricky to elicit in mice. Moreover, the stresses used, such as forced swimming, involve a behavior (swimming) not ordinarily used by mice.

A behavioral model of autism raises even greater challenges in that mentalization, skills, and language cannot be assessed in rodents. Nevertheless, Crawley (Crawley, 2007; Yang *et al.*, 2011) has been ingenious in using ultrasonic mouse socialization to index social communication and reciprocal interaction. It may be that this constitutes a useful way forward but it is difficult to see what could be learned from behavior-based models for multifactorial disorders.

It needs to be added that findings have been difficult to replicate in view of strain differences and major social context effects. While it is certainly true that there is huge genetic overlap across species, there are also important differences in the meaning of findings, as illustrated by the occasional examples of findings from animal research leading to wrong conclusions about human applicability (Academy of Medical Sciences, 2006; National Research Council, 2013).

A wide variety of animal species can inform causal research in psychopathology

It is sometimes thought that animal models have to be based on species closely related to humans, but that is not so.

Of course, the validity of findings is crucially dependent on the evolutionary conservation of key functions across species but such conservation seems to be surprisingly strong. Three examples may be given. First, John Sulston chose to use *Caenorhabditis elegans* (a tiny worm about 1 mm long) for sequencing the genome (*C. elegans* Sequencing Consortium, 1998) because it was transparent throughout its life cycle (of about 2 weeks) and it has a limited number of 302 neurons. The research provided the model for sequencing the human genome and it resulted in a Nobel Prize. *C. elegans* has also been used to demonstrate the importance of gene–gene interaction (see Chapter 24). Eric Kandel (2001) chose aplysia, the giant sea snail, because it had only about 2000 neurons and because the cells were so large that investigation of individual neurons was feasible. The research provided findings on learning and memory, which have been extremely informative about human cognitive processes.

The third example provided is the long-established and highly productive field of fruit fly (*drosophila*) genetics. Hermann Müller won the 1946 Nobel Prize in physiology and medicine for his work showing that radiation exposure produced mutations. Benzer (see Greenspan *et al.*, 2008) went on to use mutagenesis to study the biology of behavior. Fruit fly research has been highly informative in studying circadian rhythms (see Flint *et al.*, 2010 for an excellent fuller discussion of the value of *drosophila* genetics). We end this section of the chapter by referring to the work of Marla Sokolowski (Osborne *et al.*, 1997), who was responsible for identifying the genes underlying the distinction between fruit fly rovers and sitters. In subsequent work, Burns *et al.* (2012) found a significant gene–environment interaction such that early nutritional adversity in the larval period increased “sitter” but not “rover” exploratory behavior in adult life. There were also effects on the adult reproductive output of “sitters” but not “rovers” indicating a $G \times E$ on fitness. These examples demonstrate how animal models across different species can be used to identify causal risks and mechanisms.

Conclusions

The complementary use of natural experiments and animal models has provided some telling examples where generally accepted causes have been challenged and others where causal hypotheses have been strengthened. This has been particularly the case when several different designs have been used and have given rise to similar conclusions. There is an urgent need to identify genuinely causal influences, not only for scientific understanding but also to inform policy and practice. We conclude by restating that neither natural experiments nor animal models constitute a finite list of designs. Rather, they represent a style of thinking about possible causal processes and looking out for new ways in which they may be tested.

CHAPTER 13

Using epidemiology to plan, organize, and evaluate services for children and adolescents with mental health problems

Miranda Wolpert¹ and Tamsin Ford²

¹Evidence Based Practice Unit, University College London; and Anna Freud Centre; and Child Outcomes Research Consortium, London, UK

²Child and Adolescent Psychiatry, Institute of Health Research, University of Exeter Medical School, Exeter, UK

Introduction

Epidemiology is the study of who gets what (disorder, risk factor, protective factor, recovery), as well as when, where, how, and why (Evans *et al.*, 2011; Axford & Morpeth, 2013). This chapter explores how service developers, providers, and funders might use epidemiological findings and information to aid the organization, monitoring, and funding for mental health services (Williams & Wright, 1998), and highlights both the challenges and opportunities of using such data in a meaningful way. Our focus throughout is on practical advice for those of us involved in the “swampy lowlands” (Schön, 1987) of real-world practice in relation to service development for young people with problems that range from common behavioral and emotional difficulties to severe and enduring mental illness. We examine these issues in relation to a wide range of service settings across low-, middle-, and high-income countries, including specialist and targeted pediatric and psychiatric services in schools, clinics, and social care settings regardless of funding source.

This chapter does not intend to provide an extensive overview of child psychiatric epidemiological findings, which are covered in relation to particular mental health difficulties in the relevant individual chapters in this edition, nor to consider universal or primary preventions that aim to prevent the development of distress, and/or to improve well-being in children (see Chapter 17).

Why bother?

While we discuss the limitations and complexities of the application of epidemiological data to service planning, organization, evaluation, and funding, we argue that learning

from epidemiological studies provides a firmer foundation for services than historical levels of provision or politically determined policy priorities (Flisher *et al.*, 1997; Jenkins, 2001) and may provide insights into routinely gathered outcome data (Ford *et al.*, 2009).

In terms of service **planning**, basing decisions about future provision of services on those currently accessing clinical services may prove misleading. Only a small and atypical group of children currently access services, and these do not necessarily represent those most in need of such input (Angold *et al.*, 1999; Costello *et al.*, 2005; Ford *et al.*, 2008). Without reference to epidemiology, service planning is more likely to be subject to fluctuating political priorities, or skewed by responses to moral panics; whereas using epidemiological findings can aid evidence-based policy making and service planning (Davies *et al.*, 2000; Gray, 2004).

In terms of service **organization**, epidemiological data may have a role to play in focusing on particular difficulties and in holding services to account for meeting the needs of given populations. Ongoing reference to locality-based epidemiological data is essential if services are to meet the needs of groups prioritized for intervention and not overlook the needs of harder to reach communities (Burns *et al.*, 2004). Epidemiological analyses may also inform tracking and decisions in relation to individual cases once within the service. Thus, Lambert (Lambert, 2005; Lambert & Shimokawa, 2011) and others (Duncan *et al.*, 2004) are using trajectory tracking to compare progress for individual clients against anticipated progress based on data for equivalent clinical populations and using this to inform treatment decisions.

Epidemiological information may have a key role to play in terms of service **evaluation**, (Wolpert *et al.*, 2013). There is an

increasing interest in the use of epidemiological data to allow meaningful interpretation of the impact of service contact. As Clark *et al.* (2008, 631) note “[i]n the absence of randomization, one has to work very hard to demonstrate that unbalanced patient characteristics or referral practices could not have substantially influenced the treatment outcome comparison.” One approach is to use a naturalistic control group drawing on epidemiological data, such as the “added-value” score based on parental report on the Strengths and Difficulties Questionnaire (SDQ: Ford *et al.*, 2009). Using the analogy of height and weight curves, this algorithm compares the follow-up parental SDQ total difficulties score to that predicted from a largely non-treated epidemiological “control group” to estimate the impact of treatment at a group level.

As services across the world strive to find the best ways to use scarce resources to maximize public good, epidemiological data have a role to play in helping inform the development of effective **funding and payment** models and determining appropriate use of scarce resources for best outcomes.

If, however, epidemiological data are to meaningfully contribute to service planning, organization, evaluation, and funding, it is crucial that all involved remain mindful of the methodological limitations and complexities involved as well as the need to draw on other information. Rutter and Stevenson (2008) emphasize the need to consider the effectiveness of interventions, the accessibility and acceptability of services for families, as well as the skills and abilities of potential service providers. While epidemiological data are of vital importance, they should **never** be used as the sole basis for service planning, organization, evaluation, or funding.

We outline here the main methodological issues that need to be considered in epidemiological data, before turning to key findings from the data and then to the way these can be used in terms of service development.

Overview of key methodological issues

Epidemiology in child mental health generally has to rely on human report, whether self or other. There are as yet few medical markers for the vast majority of child mental health issues, so working out who has what is no simple matter. It is vital to be aware of the factors that need to be considered when interpreting epidemiological data; Box 13.1 highlights key questions for a service provider, planner, or commissioner to ask of epidemiological data and the key facts that the data establish for children and adolescents in the United Kingdom (see Box 13.2).

Who was surveyed?

Most epidemiological studies attempt to study the general population, but the method chosen to access participants, such as school or population registers, or the decision to “stratify” samples, to ensure adequate numbers of small or hard to reach groups for study, may influence who eventually participates and, therefore, the findings. Each approach has strengths and weaknesses that need to be considered when applying the findings outside the original study; it is important to ask who might have been excluded by the sampling strategy and how it might influence the findings. This issue is illustrated clearly by

Box 13.1 Key questions to ask of epidemiological data

- | | |

Box 13.2 Key epidemiological and other facts about mental health problems in children and adolescents in the United Kingdom

- | | |
|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <ul style="list-style-type: none"> Nearly 10% of children and adolescents have a diagnosable mental health disorder, the most prevalent being conduct disorder (6.6%) (Green <i>et al.</i>, 2005). Yet, less than 5% of current spending on mental health goes to services aimed at children and young people (Kennedy, 2010), and the United Kingdom continues to trail behind other Western industrialized countries on UNICEF's league of childhood well-being. The annual cost of crime in England and Wales committed by people with conduct disorder is £22.5 billion. Mental illness during childhood and adolescence results in the United Kingdom costs of £11,030 to £59,130 annually per child (Suhrccke <i>et al.</i>, | <p>2008). Children with conduct problems cost around 10 times those without conduct problems, and these costs are distributed across many agencies.</p> <ul style="list-style-type: none"> Lifetime costs of a 1-year cohort of children with conduct disorder have been estimated at £5.2 billion. The annual cost of crime attributable to adults who had conduct problems in childhood is estimated at £60 billion in England and Wales, of which £22.5 billion is attributable to conduct disorder and £37.5 billion to sub-threshold conduct disorder (Sainsbury Centre for Mental Health, 2009). |
|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|

the surprising findings of Kim *et al.*'s (2011) study of the prevalence of autism spectrum disorder among a "low-probability" general school population (1.24%) and "high-probability" disability samples (0.75%)—a discrepancy which may be at least partially explained by large differences in the gender ratio, type of disorder, and proportion with intellectual disability in the two samples recruited.

In general, people who are socioeconomically disadvantaged and in poor mental health are more likely to drop out or decline to participate (Wolke *et al.*, 2009).

Response rate, the proportion of people eligible to participate in a study who are approached and who take part, is often taken as a key indicator of how reliable the findings are, but recent empirical studies have suggested that bias due to nonresponse is not inevitably present (Groves, 2006). There is no absolute cut-point at which a response rate is definitely acceptable, but there has been a consensus that the higher the rate of participation, the less likely it is that systematic factors have influenced participation and therefore by implication, the results. Wherever possible, researchers should present their assessment of background characteristics of those who did not participate and/or those who dropped out, assess the likelihood of selection bias, and consider the potential impact of any differences on their findings.

There are particular challenges in using survey data to understand rare problems, such as psychosis or autism spectrum disorders. For example, the estimated prevalence of pervasive developmental disorders in a large British child mental health survey (7977 school-age children) was 0.9%, or 67 children (Green *et al.*, 2005). Anything other than the simplest of analyses of sociodemographic characteristics among these children is likely to be unreliable because only a few incorrectly categorized children could change or even reverse findings. A tendency to place too great a significance on findings based on very small numbers of individuals, without taking into account imprecision or uncertainty, is a very common error when applying epidemiological techniques to routine clinical practice (Goldstein, 2012). While prevalence is most often the focus of epidemiological surveys, it may also be important to consider incidence, the rate of new cases arising over a particular period of time, which can address questions such as the impact of a particular event (e.g., sudden economic downturn) on mental health, or age at which a particular problem is first likely to occur (e.g., eating disorders, first psychotic episode; c.f. Rutter & Stevenson, 2008). Given the fluctuating pattern and chronic trajectory of most types of psychopathology, it is essential to differentiate between inferences drawn from cross-sectional or longitudinal data (Kim-Cohen *et al.*, 2003). For rare disorders it may be important to supplement information from cross-sectional surveys with information from clinical samples, in particular, where disorders are so severe that clinical contact is almost inevitable, such as early onset psychosis (Boeing *et al.*, 2007). Active surveillance of incident cases across a group of clinicians can be used to gather service-relevant data on incidence and

management that avoid the selection bias inherent to case series collected at single centers of excellence (Lynn *et al.*, 2012).

Secular trends in the prevalence of a disorder over time may also be important to service provision and planning, but are often difficult to study. Retrospective reports of lifetime rates of disorder and official statistics for the prescriptions of psychotropic drugs to children, crime, and suicide suggest that the prevalence of psychopathology may have increased in the latter half of the 20th century, but changes in diagnostic criteria, methods of assessment or recording, in addition to biases inherent in retrospective reports provide alternative explanations for these reports (Fombonne, 1998; Collishaw *et al.*, 2004). For example, once the Millennium cohort reached age 7, parent reports of health-professional-assigned diagnoses of autism spectrum disorder (1.7%) were high compared to earlier studies, while reports of attention deficit hyperactivity disorder (ADHD) were low compared to American studies that used the same question (Russell *et al.*, 2013).

The selection of recent studies of populations that resemble the children they plan to serve is particularly important in relation to minority groups, as ethnic identity results from a complex interaction of culture, history, geography, and race.

Whose views were considered?

A key question to ask of any epidemiological data is whose report it is based on. Epidemiologists expect little concordance between different informants, such as children, parents, teachers, or clinicians, in relation to the nature, extent, or progress of difficulties (Verhulst & Van der Ende, 2008). This may relate not just to limitations of measurement but also to real differences in viewpoint or function in different environments. Hawley and Weisz (2005) note no agreement between child, parent, or practitioner about the problems that brought them to seek help, let alone the outcomes of any intervention for 75% of families attending a mental health service in the United States.

Parent/carer reports have often been employed in epidemiological studies, particularly where children are considered too young to provide self-reports (Levitt *et al.*, 2007). Parents' lack of awareness of internalizing difficulties and/or the impact of their own mental health status on their judgments may introduce error (Cornah *et al.*, 2003; Verhulst & Van der Ende, 2008). For children living with surrogate carers, there may be particular issues in using the report of a carer. For example, among children looked after by the state, the response from a given carer may be compromised by the loss of historical information and lack of time to build a relationship (Ford *et al.*, 2007).

Research suggests that teachers may be more sensitive reporters of children's behavioral symptoms; but less sensitive reporters in relation to children's emotional symptoms (e.g., depression, anxiety), perhaps due to the differential salience of these two indices of adjustment within the classroom (Atzaba-Poria *et al.*, 2004).

There are strong moral- and rights-based arguments for the use of child self-reports, wherever possible. However, younger children may be unreliable reporters in that they may be more likely to give socially desirable responses; they may be also less able to understand the language or the concepts used in self-report measures; they typically respond based on “the here and now”; and may be less self-aware of themselves than others around them (Van Roy *et al.*, 2008).

Expert clinical assessment is sometimes used as a key part of epidemiological surveys, but generally this too relies, to at least some extent, on parent or self-report and even clinician judgment may be subject to biases or limitations. For example, there is evidence that clinicians may rate impact differently from parents or children (Bastiaansen *et al.*, 2004) particularly in relation to long-term conditions such as autism where they tend to rate the impact higher than parents.

How was categorization made?

Different categorization systems will lead to different estimates of prevalence, as may cultural differences in perception of severity (Rutter & Stevenson, 2008; Ho *et al.*, 1996). The extent to which impairment is used may have a particularly big impact. Roberts *et al.* (1998) demonstrated that the use of impairment criteria reduced the prevalence estimates to less than half that reported if impairment were not considered, which is highly pertinent to the recent publication of DSM-5, which removes the application of impairment criteria from some diagnoses (American Psychiatric Association, 2013). Common methods to assess impairment applied in studies include scores of below 60 or 70 on the Child Global Assessment Scale (CGAS; Shaffer *et al.*, 1983) and assessments of distress, impact on activities of daily living, and to adults around the child (Roberts *et al.*, 1998). Some children may report impairing psychopathology that does not meet diagnostic criteria, either because the standardized assessment used omits to ask about the type of difficulties that they experience, or because their difficulties do not quite meet the threshold for disorders that are included in the schedule (Costello *et al.*, 2003).

Interpreting epidemiological data

The methodological issues outlined underline the importance for all involved in mental health services for children and their families to have an awareness of the complexities of epidemiological data if these are to be interpreted in meaningful ways (Goldstein, 2012). Initiatives that try to link researchers with providers of mental health services are to be welcomed as one way to encourage greater dialogue between their respective communities, as are initiatives that aim to embed researchers in practice or provide direct training in methodological understanding to service providers, planners, and commissioners. In particular, the emerging field of implementation science is helping to create greater understanding of methodological

issues and their use and impact on current service planning and provision (Eccles & Mittman, 2006).

What is need?

The issue of what constitutes need was explored in some depth in an earlier edition of this textbook (Wolpert, 2008). Four overlapping (but not synonymous) populations of children were identified as being referred to as having “mental health needs”: (a) those in difficult circumstances, (b) those at risk of developing diagnosable mental health problems, (c) those with diagnosable mental health problems, and (d) those with levels of impairment resulting from mental health issues that make it difficult for them to function in their community or culture (Wolpert, 2008).

Determining the need for each of these groups and planning services accordingly draws on different sets of epidemiological data and raises different issues.

What can epidemiology tell us about levels of need?

There are epidemiological data relevant to each of the groups identified. In terms of those in “difficult circumstances,” there is evidence that too many children in the world could be so categorized, and despite government and non-governmental organization (NGO) prioritization of child health and welfare (e.g., Bill Gates Foundation <http://www.gatesfoundation.org/What-We-Do/Global-Development/Maternal-Neonatal-and-Child-Health>, NSPCC <http://www.nspcc.org.uk/>) world events such as war, famine, and financial meltdown are only likely to swell their numbers. Latest estimates suggest that there are over 14 million AIDS orphans in Africa (World Health Organization, WHO, 2005), 12 million children living below the poverty line in the United States (WHO, 2005), and 3 million girls across the world at risk of suffering genital mutilation every year (WHO, 2008). Not all of these children will have mental health issues and how to best target those who do remains a key challenge.

While some factors related to difficult circumstances may increase the risk of developing diagnosable mental health problems, risk may also be associated with other individual and interpersonal factors such as brain injury, low birth weight, special educational needs, or poor parental mental health (Goodman & Scott, 2005; Rutter & Stevenson, 2008). The number of risk factors included and the level of risk assessed will influence the proportion of children who fall into this category in the general population.

Reviews of epidemiological surveys spanning several countries and over half a century suggest that between 3% and 22% of school-age children can be categorized as having psychiatric disorders (Canino *et al.*, 1995; Offord, 1995; Roberts *et al.*, 1998; Costello *et al.*, 2005). There may be some differences across

countries and contexts, with slightly lower rates found in India and Norway, for example (Malhotra *et al.*, 2002; Heiervang *et al.*, 2007), and slightly higher in Brazil, Bangladesh, and Russia (Fleitlich-Bilyk & Goodman, 2004; Mullick & Goodman, 2005). While it is hard to separate out genuine differences from differences arising from methodology, cross-country comparison is more meaningful when the same instruments have been used, linguistic issues aside. Thus, in a predominantly urban municipality in Brazil, researchers identified that prevalence among 7- to 14-year-old school children was 13% using the same instrument (Development and Well-being Assessment; DAWBA) as that employed in the British national survey (Meltzer *et al.*, 2000; Ford *et al.*, 2003), which reported a prevalence of 10% in school-age children. A comparable study of the same age group in a Russian city (Goodman *et al.*, 2005) produced a prevalence of 15.3%, which is very similar to the prevalence of 15% reported among 5- to 10-year-olds in Bangladesh (Mullick & Goodman, 2005).

In the seminal Great Smoky Mountain study, Angold *et al.* (1998) found that half of all children attending a US clinic did not meet diagnostic criteria, but half of these were significantly functionally impaired. High levels of impairment and impact for key difficulties appear to predict later outcomes and potential cost to society. Over half of all adult mental health difficulties start before the age of 15 (Kim-Cohen *et al.*, 2003), and without appropriate intervention can lead to significant long-term impairment. Thus, impairing behavioral disturbance in children has been linked to severe and long-standing outcomes in adult life, including drug abuse, criminal activity, and poor physical health (Broidy *et al.*, 2003). The cost to the state of an unaddressed conduct disorder over a 7-year period in the United States has been estimated to exceed \$70,000 largely in costs related to criminal behavior (Foster & Jones, 2005).

What can epidemiology tell us about planning to meet need?

For those exposed to extreme poverty, war, torture, or famine (WHO, 2005), the optimal targeting of limited mental health services is a key challenge that should be tempered by an understanding of the possible iatrogenic effects of misdirected intervention. The demand for specialist mental health provision must be:

set in the context of other, sometimes competing, “needs” such as the primary need of children to be nourished, sheltered and protected; their need not to be stigmatized or miss education; and their need not to receive inappropriate, ineffective or harmful treatment. (Wolpert, 2008: 1158).

A focus on mental health at the expense of other provision may be an unhelpful drain on resources. For example, well-intentioned NGO support was provided following a disaster to provide “interventions for post-traumatic stress disorder

(PTSD)” which in fact disrupted and undermined concurrent relief efforts (WHO, 2005).

Where resources permit, it may be advantageous to provide targeted services for these groups to try to promote resilience and forestall the development of later mental health difficulties for those at risk, given the correlation between key risk factors and later psychopathology. Early intervention and support for young people living with parents with severe and enduring mental health issues may be a sensible starting point (Cooklin *et al.*, 2012). Targeted interventions in schools for those at risk of or with mental health problems may help reduce levels of behavioral problems (Wolpert *et al.*, 2011). However, agencies other than mental health services may have a crucial role to play in this kind of provision, such as educational support to manage special educational needs to avoid secondary impacts on mental health, or better housing or other welfare interventions.

The types of disorders identified in epidemiological studies and their relative occurrence are broadly comparable across the world, allowing for cross-country learning and advice, and prevalence does appear to be pretty universally linked to levels of deprivation and other risk factors, suggesting that it is entirely appropriate to target resources on the most deprived groups, provided that interventions are effective in this population.

Service use now

Comparisons of rates of service contact across countries are complex due to variations in the finance and organization of services. Studies vary in how different services are classified; for instance, school counsellors have been conceptualized as a contact with education or mental health services in different studies (Burns *et al.*, 1995; Leaf *et al.*, 1996; Ford *et al.*, 2007). Comparisons between studies about the rates of service use should therefore be made cautiously, but Table 13.1 clearly illustrates that only a small proportion of young people with a psychiatric disorder reach mental health services and that many others are supported by other services, while a large proportion receive no input at all (Ford *et al.*, 2008).

Contact with a service does not necessarily imply that needs are being met, as for some disorders effective interventions have yet to be identified and the small literature on the effectiveness of routine services provides inconsistent evidence of positive outcomes (Harrington *et al.*, 1999; Andrade *et al.*, 2000; Angold *et al.*, 2000; Weisz & Jensen, 2001; Axford & Morpeth, 2013).

What factors predict access?

The presence, severity (including comorbidity), and impact of difficulties are consistently related to contact for mental health problems with all types of services globally (Staghezza-Jaramillo *et al.*, 1995; Zwaanswijk *et al.*, 2003; Ford *et al.*, 2008). Contact with key gatekeepers, such as primary health care and schools,

also strongly predicts service contact across most services (Ford *et al.*, 2008), as does the perception and health literacy of the young person and/or parents and teachers in many, but not all, studies (Garraalda & Bailey, 1988; Staghezza-Jaramillo *et al.*, 1995; Zahner & Daskalakis, 1997; Wu *et al.*, 1999; Sourander *et al.*, 2001; Ford *et al.*, 2008). Externalizing symptoms are more strongly associated with service use than internalizing symptoms (Jones *et al.*, 1987; Wu *et al.*, 1999). As Rutter and Stephenson (2008) point out, different communities may be more sensitive to some behaviors than others. In their comparisons between Thailand and the United States, Weisz and Eastman (1995) found that behavioral problems were more likely to lead to clinic referral in the United States than in Thailand, whereas the reverse was true for emotional problems. Referral patterns may also be influenced by the context of what other support is available. Thus, in the United Kingdom, when comparing children who were and were not referred to specialist services from primary care, Garraalda and Bailey (1988) found that the nonreferred children had made significantly more primary care visits than the referred children, highlighting the important role of primary care as a provider for these children in this context.

Poor physical health, poor academic performance, nontraditional family structure, parental psychopathology, and adverse life events are all frequently associated with service contact, although they are also strongly associated with the presence of a psychiatric disorder (Jensen *et al.*, 1990; Staghezza-Jaramillo *et al.*, 1995; Verhulst & van der Ende, 1997; Zahner & Daskalakis, 1997; Gasquet *et al.*, 1999; Sourander *et al.*, 2001; Zwaanswijk *et al.*, 2003; Ford *et al.*, 2008). The area where the family resides may influence service contacts, with several authors reporting that service provision does not relate to the level of need across the areas studied (Boyle & Offord, 1988; Thomas & Hargett, 1999; Sturm *et al.*, 2003; Ford *et al.*, 2008).

Most investigators reported no statistical association between service use and socioeconomic status, while equal numbers of studies report significantly more contact from advantaged or disadvantaged groups, which may be partly explained by families of different socioeconomic status accessing different settings, such as middle-class families opting for education-based services (Jensen *et al.*, 1990; Burns *et al.*, 1995; Staghezza-Jaramillo *et al.*, 1995; Zahner & Daskalakis, 1997; Gasquet *et al.*, 1999; Laitinen-Krispijn *et al.*, 1999).

Studies examining ethnicity are equally complex to interpret, and evenly divided between over- and underrepresentation of children from ethnic minorities (Burns *et al.*, 1995; Zahner & Daskalakis, 1997; Wu *et al.*, 1999; Angold *et al.*, 2002; Kataoka *et al.*, 2002; Zwaanswijk *et al.*, 2003).

a number of grounds. Firstly, longitudinal epidemiological data show that many diagnosable mental health problems improve without intervention and rushing to intervene may harm rather than help. Moreover, the dangers of false positives with the potential to distress and stigmatize and the costs of unwarranted assessment and intervention combine to suggest that this approach is unwise and unsafe at this stage in our knowledge.

Different countries have varied service organizations; the only universal finding being that wherever child mental health services are located, boundary issues always arise (Wolpert, 2008). In some areas of Europe, (e.g., Switzerland and Hungary) and in some parts of the United States, most child mental health services are under the auspices of education. This may increase access and reduce stigma, but can make coordination for older adolescents or those with more severe mental illnesses problematic. Learning from epidemiological incidence data that pinpoints late adolescence as a key period of transition and difficulty for many young people, a number of countries have now started to focus on dedicated youth services that stretch from adolescence to early adulthood to encourage flexibility for 18- to 20-year-olds (Hazell, 2005) and development of specialist services for this traditionally underprovided group (Patel *et al.*, 2007). The traditional split between child and adult mental health services places a transition at the peak age of incident severe mental illness, and the study of trajectory into adulthood is complicated by a disjunction in the philosophy and methods of both practitioners and researchers with these populations (Singh *et al.*, 2010).

Constant checking of access against anticipated need for targeted local populations is recommended to ensure equitable access for particularly vulnerable or hard to reach groups. Local services should undertake their own local epidemiological studies to ensure appropriate targeting of need within their area. While we would recommend use of epidemiological data in general, it is important to note in this context that a universal finding in both developing and industrialized countries is the relative lack of services compared to the level of need and that “services everywhere fall well short of even a conservative estimate of requirements” (Rutter & Stevenson, 2008). Thus, attempts to spend time and energy on complicated analysis of local need may not be warranted at this stage, particularly in light of the resources available, as well as the methodological issues discussed. It may be more feasible to use the available epidemiology supplemented by local knowledge where this deviates from the norm.

Using epidemiology to determine organization

Epidemiological surveys can be used to screen for need and target treatment. We would argue against this approach on

Using epidemiology to determine funding arrangements

The current financial climate and the resulting restriction in resources have resulted in a particular emphasis on the use

of epidemiological data to target service provision. Increasingly, there is an emphasis on service providers agreeing to realistic goals with children and families and working toward these goals in a considered fashion to prevent mission creep as providers get ineffectually caught up in trying to solve multiple complex problems (Weisz *et al.*, 2011; Law, 2012). One suggestion is that a more explicit recognition of what can be achieved and what is realistic to expect be combined with progress tracking against anticipated trajectories of change in order to identify and prevent drop out from “off track” cases (Lambert, 2005) and make the most efficient use of services (Miller *et al.*, 2006).

There are national and international initiatives to find the best and most economic ways of funding child mental health. The proportion of the overall health budget allocated to mental health ranged from 9% in Egypt to 0.01 % in Kenya (WHO, 2005), and the child mental health budget is likely to be a small proportion of that, for example, in the United Kingdom it is less than 5% of the overall mental health spend.

In recent years, there has been an interest in developing prospective, activity-based payment systems, in which providers are paid in advance, on the basis of their likely caseload. These have been referred to as “**casemix**,” or “**payment by results**” systems (<http://pbrcamhs.org/>). This type of a fee-for-service system applies data (often based on the previous year’s caseload) to predict the funding needed for the following year (Mason *et al.*, 2011). Attempts to develop a casemix payment system for mental health provision, which classifies service users according to similarities in presentation (e.g., diagnosis, severity, functioning), are currently under way in Australia, New Zealand, and England but none have yet implemented these. Canada has implemented a casemix payment system for adult inpatient mental health treatment, but this is limited to treatments that are considered “medical” mental-healthcare. The Netherlands has developed a similar system but expanded it to include child and adolescent and “nonmedical” psychiatric care (Mason *et al.*, 2011). In child mental health, the complexities of attempting to develop such a system are compounded by the amount of indirect work done by service providers that is all too often not adequately captured in routine data collection.

Using epidemiological data to understand outcomes of treatment for teams and services

Evaluation of services is increasingly focused on the use of patient-reported outcome measures (PROMs) and/or patient-reported experience measures (PREMs). The use of epidemiological data to inform interpretation of these data involves a decision about what constitutes meaningful (or clinically significant) change, which raises three main issues.

The first issue is whether the change in an outcome measure is greater than is expected by chance variation given the limitations

of the measure used. The Reliable Change Index (RCI) aims to assess the amount of change required in an outcome measure to be reasonably confident that the magnitude of change observed is not solely attributable to measurement error and can be calculated in a variety of ways (Jacobson & Truax, 1991). The RCI for the parent SDQ, for example, for a UK population is 7 points, a parent total difficulties score has to move by 7 points to suggest a “reliable change.” A more pertinent issue is whether the change recorded is meaningful for the quality of the individual’s life. One metric developed for this involves movement from high-symptom scores pretreatment to scores that fall within the nonclinical sample range after treatment. Some have argued that reliable change and movement across the clinical cut-off need to have occurred for clinically significant change to be deemed to have taken place (<http://www.iapt.nhs.uk>). However, it is not yet clear if this is an appropriate standard to set, and for some conditions, such as autism spectrum disorder, this is probably unrealistic (Wolpert *et al.*, 2013).

It is also important to know whether change might have occurred spontaneously if no intervention had been offered. The SDQ added value score attempts to adjust for regression to the mean, random fluctuation and attenuation and was able to replicate the changes seen in a randomized controlled trial when applied to the intervention and waiting list control arms separately (Ford *et al.*, 2009). The approach taken by CAMHS Outcomes Research Consortium (CORC) is to produce annual reports of aggregated outcomes (both PROMs and PREMs) for teams of clinicians working within the collaboration. These are then compared with aggregated outcomes for consortium members as a whole and any areas of statistically significant difference noted.¹ Members are advised that these should be interpreted in terms of their local knowledge and triangulated with other data. Thus, a series of hypotheses can be tested to explore any differences to check if they are the result of differences in methodology, population being worked with, data entry errors, or genuinely reflect differences in outcomes for similar groups of children and families.

When viewing this sort of data it is important to avoid over-interpretation when datasets are small and what appear to be large variations in outcomes between services may, in fact, reflect normal variation between data points to be expected when small numbers are involved. Using funnel plots to map comparative data to ensure meaningful interpretation may be very helpful in this regard. These plot the statistic of interest, for example, the mean outcome from a service, against a measure of its precision such as the number of children contributing data (Spiegelhalter, 2005). When confidence intervals of the mean (which become narrower as the sample size increases, producing a funnel shape) are applied, it is possible to ascertain which services appear to have unusually good and unusually poor scores.

¹ CORC is looking to modify this model further by making comparisons more specific between services in similar contexts and with similar populations of service users.

Conclusion and further directions

Epidemiological data may play a central part in terms of planning, organizing, evaluating, and commissioning services. These data may be key to aid evidence-based policy making and service planning (Davies *et al.*, 2000; Gray, 2004), and have a role to play in helping to determine focus in a particular area and in holding services to account for meeting the needs of given populations. Epidemiological analyses can inform decisions in relation to individual cases once within the service and to overall evaluation of the service. Epidemiological data could inform the development of effective funding and payment models and determine appropriate use of scarce resources for best outcomes.

However, if such data are to meaningfully contribute to any of these aspects, it is crucial that all involved remain mindful of the methodological limitations and complexities involved as well as the need to draw on other relevant information covered in other chapters in this volume, including information as to the effectiveness of interventions, acceptability of services to potential service users and their parents, as well as the skills and abilities of potential service providers. We would argue that while epidemiological data are of vital importance, they should never be used as the sole base for service planning, organization, evaluation, or funding.

CHAPTER 14

Evaluating interventions

Helena Chmura Kraemer^{1,2}

¹Stanford University (Emerita), Stanford, CA, USA

²Department of Psychiatry, School of Medicine, University of Pittsburgh, Pittsburgh, PA, USA

Introduction

“How well will this treatment work for this patient/for me?” is the question to which every patient and his/her clinician wants answers, but one research cannot answer. Yet in absence of research, clinicians can only guess, and patients take the consequences of poor decision making. The question research can answer, however, is “How well will this treatment work for patients *like this* patient?,” by taking a sample of patients from a population like this patient, and assessing how well the intervention (T) works for patients in that population. Depending on how well the patient fits within that population, such a result gives the best estimate of the likely impact on the individual patient, the goal of evidence-based medicine. The methodology of evaluating interventions focuses on what must be done to bring that answer as close as possible to accurately and precisely answering the first question.

Many books and papers have been written on this subject. The many ways such research can be conceived, designed, executed, reported, and processed could not possibly be covered here. In what follows, after the basic principles are articulated, the focus is on areas where errors are most likely.

The fundamental principles

The control/comparison groups

How well a treatment works is not answered by simply prescribing T to the patients in the sample and observing the subsequent response. What appears to be a good response to T may actually be no better than what would have occurred had T not been given. In short, one cannot attribute the observed response to the *effect* of T, nor can one judge the *response following T* as beneficial, neutral, or harmful, without comparison with another intervention, a control or comparison intervention (C) that represents what would have happened had T not been

prescribed. C could be absence of any treatment, a placebo, a waiting list, “treatment as usual,” standard of care, an active comparator, and so on. What C should be in any particular clinical trial is a contentious question, but the basic principle is that *there must be a control/comparison group* in order to evaluate any intervention.

Measuring the effect of T versus C

Traditionally, what is required in research is to show that there is some difference unlikely due to chance between T and C, a “statistically significant difference.” There are long-acknowledged problems with this approach (Shrout, 1997; Hunter, 1997). A better premise: The goal of clinical research comparing T and C is to estimate an effect size showing how much more likely is a clinically preferable response from a patient treated with T than from one treated with C. A number of effect sizes might be used, but here the focus will be success rate difference (SRD), where $SRD = \text{Probability}(T > C) - \text{Probability}(C > T)$, where “ $T > C$ ” means that if one randomly sampled a patient treated with T and compared the response with another treated with C, the response of the T-treated patients would be clinically preferable to that of the one treated with C. SRD ranges from +1, when every patient treated with T has a response preferable to every patient treated with C, to –1, when the reverse is true. SRD equal to zero indicates clinical equivalence of T and C.

The traditional goal of showing a “statistically significant effect” is equivalent to showing that SRD is not equal to zero. Instead, we want to estimate SRD (with a confidence interval to show the precision of such estimation), in order to judge, not merely whether SRD equals zero or not, but (1) whether the study is well enough designed to give a reasonably precise estimate of SRD (indicated by the length of the confidence interval), and (2) if so, whether SRD is large enough to be considered clinically significant, large enough to convince patients/clinicians that selecting one intervention over the other is likely to make a real difference to patient outcome.

Randomization

To interpret the SRD comparing T versus C, the two samples must obviously be drawn from the *same* population. When, for example, patients who choose T are compared with those who choose C, the two samples may represent different populations, because there are often selection factors (many unknown) that differentiate the two groups. To guarantee that the two samples are drawn from exactly the same population, one sample is drawn from the relevant population, and these patients are *randomly* assigned to T or to C.

It is important to understand that randomization is a systematic, not a haphazard, procedure and that it does not produce two *matched* samples from the population. In fact, 5% of all independent baseline variables would be expected to significantly differentiate the two randomly assigned treatment groups at the 5% significance level. Two treatment groups too well matched at baseline are almost as questionable a situation as two treatment groups differing greatly at baseline. Both suggest that some non-random selection took place.

“Blinding”

Because the assessment of response can easily be colored by knowledge of which intervention was delivered to which patient, some effort must be made to minimize bias resulting from this knowledge. Otherwise, any differences between T and C may be in the eye of the beholder rather than in that of the patients. One such effort is termed “blinding,” ensuring that those involved in assessing individual responses should not know which intervention was received.

Analysis by intention to treat

The purpose of randomization is to ensure that the T and C groups are two random samples from the same population. Any removals postrandomization from either treatment group, either by choice of the patient (dropout, noncompliance) or by choice of the clinical researchers (a focus on completers) can reintroduce the selection bias that randomization is designed to preclude. Attrition may reflect the patient’s response to treatment, and what factors determine attrition may be different in T and C. Thus, every patient randomized must be included in the final evaluation of the two treatments: analysis by intention to treat.

Ethical issues/clinical equipoise

Patients likely to be harmed by either of the treatments or by the procedures in the study must ethically be excluded from eligibility. Not only must the patient be informed of what the treatments are, of what they are expected to experience during the trial, but of any known ill effects of participation. Ethical considerations mean that a patient cannot be included in a trial without *informed* consent.

Moreover, it is not ethical for a researcher already convinced of the answer to the research question to conduct an RCT: *clinical equipoise*. Ethicists can argue the ethical bases for the necessity for clinical equipoise, but from the point of view

of a biostatistician, the simple fact is that if the researcher is convinced of what the “right” answer is, she/he is prone to biasing all the decisions in designing, conducting, analyzing, and interpreting the results of a study in that direction. Thus, before considering an RCT, the researcher must have rationale and justification for proposing his/her hypothesis, but must also have reasonable doubt as to whether that hypothesis is true or not. Then she/he must design, conduct the trial, analyze the data, and report the results in such a way as to assure that the conclusions are the correct ones, even if they indicate that the researcher’s hypothesis was false.

Basic principles of the randomized clinical trial

The basic principles of randomized clinical trials (RCTs) are clinical equipoise, population specification, sampling, randomization to a well-defined T and C, blinding, analysis by intention to treat, fair and unbiased conduct of the trial, and interpretation of trial results. Each of these principles was articulated because earlier trials failed in one way or another, and each is ignored at the risk of incurring failures in future studies. Generally, the RCT is considered the “gold standard” for evaluation of treatments. RCTs are challenging, time-consuming, and costly. Many argue that RCTs are not necessary, that equivalent results can be obtained from other, less rigorous, approaches. Before we consider options available to design valid and powerful RCTs, let us briefly consider certain alternatives.

Alternatives to RCTs?

The pre-post design

Since the primary goal is only to show that T improves treatment response, why not simply assess the clinical status of patients sampled from the relevant population before start of treatment, and then after treatment, and see whether there is/is not an improvement? No need for a control group, randomization, “blinding,” and all those messy RCT challenges!

However, even when the clinical status of the patient does not change, one is likely to see what appears to be improvement. Statistical regression to the mean (Campbell & Kenny, 1999) occurs because those who are sampled are assessed to be reasonably highly symptomatic. However, selection of such patients on the basis of a less than perfectly reliable assessment of symptoms means that false positives are included and false negatives excluded from the trial. Subsequent assessment of response will likely correct measurement errors, and the patients as a group will appear to move toward the true value (i.e., appear improved) even in absence of improvement.

Moreover, because assessors know that all patients are given T and expect to see improvement, they often see improvement even when there is none. There may be measurement drift over time, with criteria less stringent at endpoint than at entry. If the patients are not “blinded” to the fact that all are treated, their own expectation effects may produce an appearance of

improvement when there is none. Finally, patients may actually improve even without effective treatment, that is, what one sees is not the result of treatment but a natural and inevitable occurrence.

The combination of all of these artifacts means that it is common to see what appears to be improvement when there is none. In many cases, an RCT that results in a “nonstatistically significant result” is misinterpreted as having equally beneficial effects in both T and C because the pre-post change in both groups is found “statistically significant,” when all this means is that the same statistical artifacts affected both groups. In short, pre-post trials are not a suitable alternative to RCTs.

Cross-over designs

A more contentious and appealing alternative to RCTs is a cross-over design. In this design, patients are randomly assigned either to T and C in the first time period (a standard RCT). A suitable “wash-out” period follows. Patients assigned to T in the first time period are assigned to C in the second and vice versa. Thus, each patient “serves as his/her own control” in that we can compare each individual patient’s response to T and to C directly.

This design has attractive features. It is often easier to recruit patients into such a design, since each patient is assured of getting the “preferred” treatment. It is easier to avoid attrition in the first period, because patients who do not have a good experience may hope that the second period will be better if they persist.

However, the validity of conclusions here depends on complete absence of carry-over effects from the first period to the second, and then crucially on all patients completing both treatment periods. The assumption that all patients have returned to “virgin” status at the end of the wash-out period seldom holds. With drug treatments, the metabolites of the first drug may still be active when the second drug is given, unless the wash-out period is very long, so long that the clinical status of the patient may have changed. It is difficult to imagine that any intervention that involves learning (e.g., psychotherapy or an educational intervention) can ever be “washed out.” Moreover, patients who experience benefit in the first period may be reluctant to have that effect “washed out”; patients who experience no benefit in the first period may become discouraged and drop out, particularly if the “wash-out” period is long.

When a cross-over design is used, there must be a careful check for absence of carry-over effects (Brown, 1980; Fleiss *et al.*, 1985). If such effects are detected or strongly suspected, the fallback position is to ignore the second time period and treat the first time period as a simple RCT. However, that will mean wasted time, effort, and resources, and will have put an unnecessary burden on the patients involved in the study.

There is a middle ground that preserves some of the advantages of the cross-over design, but avoids the almost inevitable pitfalls. One might design a standard RCT (the first time period), but offer patients the option, once that period is over, of moving to

the alternative treatment, if they so choose. Then there need be no wash-out period, and no necessity for data recruitment and retention is maintained. Patients may choose not to go to the second time period, in which case, whether they accept the burden is their choice, and many will choose not to do so, decreasing waste in time, effort, and resources.

Natural experiments, observational studies, quasi-experimental designs

What if we could not randomize? What if we had access only to nonrandomized samples of patients with T and with C? Could we not compare these groups to draw inferences about the effect of T versus C?

The answer, as many have argued, is that if those samples are representative of the *same* population, of course one can, for, that would then be equivalent to an RCT. Indeed, if we knew what factors relevant to treatment response differentiated the two groups and had good measures of them, there are statistical methods that might remove most or all of the sampling biases (e.g., Rosenbaum & Rubin, 1983; Jo & Stuart, 2009). There are methods designed to bring the credibility of inferences as close to those resulting from RCTs as possible (see Chapter 12).

Effect sizes. Not *P*-values

An effect size is a population parameter that indicates the strength of an effect in a way that can be practically or clinically interpreted (Kraemer & Kupfer, 2006). The most common effect size in RCTs is Cohen’s *d* (Cohen, 1988), the mean difference between the two treatment group means divided by the assumed common standard deviation within the two groups. The problem is that *d* is meant to compare two normally distributed responses with equal variances. Actual outcome measures often do not satisfy this assumption.

SRD, as defined, can be used with any outcome measure on which responses can be compared, a requirement for any outcome measure in an RCT. If the assumptions underlying Cohen’s *d* hold, then $SRD = 2\Phi(d/\sqrt{2}) - 1$, where $\Phi()$ is the cumulative standard normal distribution. Thus *d*, when appropriate, is not lost, but simply rescaled.

Another effect size attractive to clinicians, patients, and policy makers is number needed to treat. Since $NNT = 1/SRD$, NNT is again merely a rescaling of SRD. NNT is the answer to the question: How many patients would have to be treated with T to have one more “success” than if the same number were treated with C. Thus, if $NNT = 1$, every patient treated with T has response clinically preferable to every patient treated with C ($NNT = -1$ reverses T and C). Infinite NNT means that the two treatments are clinically equivalent.

Odds ratio is also commonly used as an effect size when the outcome is binary: success/failure. If *s*₁ is the success rate in T and *s*₀ the success rate in C, then odds ratio = $s_1(1 - s_0)/((1 - s_1)s_0)$, whereas SRD here equals $s_1 - s_0$. There is no

problem with interpreting odds ratio = 1. This indicates clinical equivalence of T and C and can only occur when $SRD = 0$. However, what of any other value, say, odds ratio = 25? This can result with $s1 = 2.4\%$ and $s0 = 0.1\%$, in which case $SRD = 0.023$ and $NNT = 43$, a trivial effect size by usual standards. It can result with $s1 = 96.2\%$ and $s0 = 50.5\%$, in which case $SRD = 0.457$ and $NNT = 2.2$, a large effect size by usual standards. Such a situation can only confuse the interpretation of RCTs for clinical application.

The difficulty with the odds ratio has to do with division by near-zero numbers. If either $s1$ or $s0$ is extreme, very near zero or very near 1, the odds ratio tends to “explode,” becoming very large even when the clinical effect may be trivial. When neither $s1$ nor $s0$ is extreme, then SRD is approximately equal to $(\sqrt{OR} - 1)/(\sqrt{OR} + 1)$ (Kraemer & Kupfer, 2006). In general, odds ratio cannot be interpreted as indicating the effect of treatments for clinical decision making and should not be used as an effect size for RCTs (Sackett, 1996; Newcombe, 2006).

There are three different effect sizes of concern in any RCT: the *true effect size* in the population which is never known exactly, the *estimated effect size* after completion of the RCT which provides information about the true effect size and upon which the conclusions of the RCT are based, and the *critical effect size* which is a setting of the threshold of clinical significance upon which power considerations are based before the RCT, and upon which interpretation of the clinical significance of the T versus C choice is based after completion of the RCT.

Cohen, in discussing the role of Cohen's d in power considerations (Cohen, 1988), suggested that $d = 0.2, 0.5, 0.8$ were small, medium, and large effect sizes. These standards, widely used, correspond to $SRD = 0.11, 0.28, 0.43$ or $NNT = 8.9, 3.6, 2.3$. However, Cohen rightly warned that any such standards should not be reified. What is clinically significant may change from one situation to another, depending on the severity of the disorder being treated, the consequences of inadequate treatment, the costs and risks of the treatment itself, the vulnerability of

the population, and so on, and is determined by perusal of the exploratory materials in the specific context of the research.

Exploratory activities, pilot studies, and RCTs

In Figure 14.1 is an idealized depiction of the scientific method as applied to RCTs. The process begins with exploratory/hypothesis-generating activities: review of the literature, current theories, clinical observations and experience, results from animal models or tissue research, secondary analysis of existing datasets, and so on. In research areas close to the “cutting edge,” where there is little in the existing literature, studies specifically designed, to generate hypotheses for testing in future studies (unfortunately derided as “fishing expeditions”) might be proposed and executed. From this work, the theoretical rationale and empirical justification for a hypothesis is developed, as well as the information needed to design a valid and powerful RCT to test that hypothesis, and finally an indication of the critical effect size in the context of this hypothesis.

Once the hypothesis is formulated, the focus is on designing a valid and powerful RCT. When that is done, there are often questions about whether certain aspects of the design can be done as proposed in the milieu in which the RCT is to be done. Can one really recruit as many patients per year as proposed? Can T and C be delivered as per protocol? To find out after the RCT is launched, that the study is not feasible, is problematic. Thus, often a pilot study is proposed to test the feasibility of what is proposed, to develop treatment and measurement manuals, to train treatment deliverers and assessment staff, in essence to debug what is proposed in order to guarantee the feasibility of the RCT. Once that is done, the RCT can be executed as designed (i.e., with fidelity), and analyzed as proposed.

It should be noted that pilot studies, so defined, perform a crucial function in ensuring that RCTs are successful, but are not

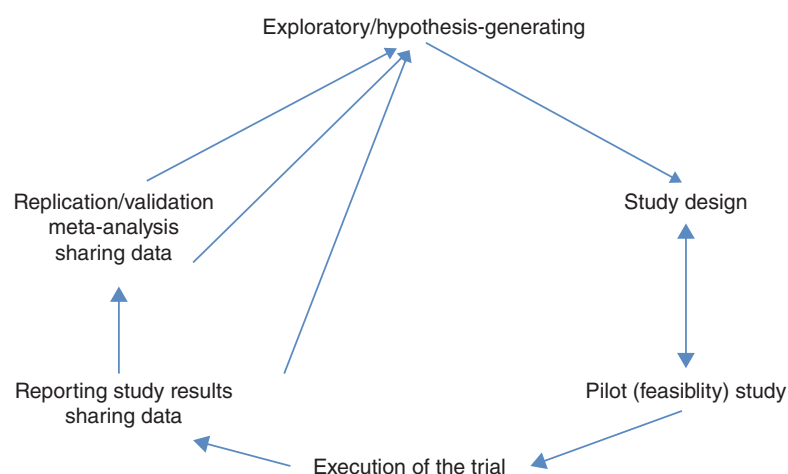

Figure 14.1 An idealized version of the application of the scientific method to evaluation of interventions.

themselves meant to test or to estimate effect sizes. Often the results of a pilot study are not publishable in that they relate to local conditions rather than to scientific questions that generalize across sites or time. It is an unfortunate fact that the term “pilot study” is often preempted to mean a small, badly designed, inadequately powered study, one that cannot provide any trustworthy estimate of the effect size of treatment, either for use in subsequent power calculations or to assure review committees that the RCT will be successful in identifying a viable intervention (Kraemer *et al.*, 2006).

Once the RCT is completed, three things should occur: (1) the conclusions concerning the hypothesis tested are presented; (2) the dataset is explored both to gain a greater understanding of issues related to that hypothesis, and to develop hypotheses that might be important for future research; (3) the dataset is shared with other researchers both to allow a check of the internal validity of the conclusions drawn, and to enrich the resources for exploration in general. In short, the beginning and end of an RCT lie in exploratory data analysis. Without these activities, hypotheses proposed are often weak, the designs used to test the hypotheses lack power, and RCTs are more likely to fail. Let us now focus on the design, execution, and reporting of RCTs.

Formulating the hypothesis

Efficacy versus effectiveness

Efficacy versus effectiveness considerations are crucial to articulating the hypothesis and designing the RCT appropriately (Hoagwood *et al.*, 1995; Weisz *et al.*, 2013). These terms do not refer to two specific types of studies but to a continuum of approaches. An efficacy study asks whether $T > C$ under ideal circumstances, whereas an effectiveness study asks whether $T > C$ under the usual circumstances. The decision as to where on the continuum between “ideal” and “usual” an RCT hypothesis is placed determines all research design decisions.

Population and sampling:

The results of any research study apply to the population represented by the sample. A study sampling a clinic population is unlikely to yield the same results as that sampling a community population. An RCT done at one site does not necessarily yield the same results as exactly the same RCT done at another. An RCT done in 2000 does not necessarily yield the same results as one done in 2010. How, where, and when a research study is done always determines the generalizability of its conclusions.

In an efficacy study, the inclusion/exclusion criteria are usually very narrowly set to include only those patients likely to support the hypothesis. One might exclude those who are too symptomatic or not symptomatic enough, those with comorbidities, children whose parents themselves have psychopathology, or other indications that would presage lack of cooperation, or limited response to treatment. The treatment would be delivered under optimal circumstances, often requiring specially trained

physicians with access to resources not available to ordinary clinicians. Because the true effect size is likely to be large, the sample size necessary for adequate power will tend to be small. Thus, the time and cost of the study will also be low, but generalizability of results limited.

In contrast, in an effectiveness study, only patients one could not ethically include would be excluded, to be as representative as possible of those for whom clinicians might need to make a decision between T and C. The sample randomized would be heterogeneous, compliance might be a problem, and dropout more likely. The clinicians would operate as clinicians are likely to in practice. The sample size then would necessarily be much greater, as would the time, cost, and difficulty. However, the answer would be more relevant to actual clinical decision making (Weisz *et al.*, 2013).

Logically, the very first RCTs comparing a new treatment T against C should probably always be efficacy studies. If T is not substantially better than C in ideal circumstances, it is hardly likely to be better under usual circumstances. However, before dissemination of a treatment, effectiveness studies are badly needed.

Multisite RCTs

It is often difficult to generate a large enough sample size at any one site, the usual argument for a multisite RCT, one in which exactly the same RCT is conducted at more than one site. An even more powerful argument for multisite RCTs stems from the observation that the conclusions of an RCT done at one site do not necessarily generalize to those at other sites. A multisite RCT affords the opportunity to test whether generalization will occur at least to sites represented by those participating in the RCT.

Consequently, in analyzing results, site, choice of treatment, and their interaction must be assessed (Kraemer & Robinson, 2005). Testing the site by treatment interaction is a test of the null hypothesis that the effect sizes comparing T and C are the same at all sites, and the main effect of treatment tests whether the *average* within-site effect size over sites is zero. If there is evidence of heterogeneity of treatment effect sizes across sites, the separate effect sizes would need to be reported and possible sources of heterogeneity explored. Otherwise, the pooled within-site effect size and its confidence interval would be reported. The pooled within-site effect size is not generally equal to the overall effect size if site is ignored in the analysis. Many multisite studies in the past have ignored site or site by treatment effects, and thus, in many cases, misreported their conclusions.

Individual versus cluster randomized studies

Generally, in RCTs, T is delivered to each patient individually, and no patient influences another patient's responses. However, there are situations in which T is delivered to groups (therapy groups, classes, families, etc.). Then the unit of randomization and of analysis must be the group, not the individual. For individual interventions, analytic procedures are based on the assumption of independence of responses. When there

are between-patient interactions that might affect response, p -values, parameter estimates and confidence intervals based on the usual statistical methods are biased. In such cases, specialized statistical methods must be used to account for the between-patient correlations (Murray, 1998).

Designing the RCT

Choice of control group

What does it mean “if T were not given”? That is the question that should decide the choice of control group, C. In efficacy trials, the choice for C is often an inert placebo, for this gives the easiest challenge to show some effect of T. Otherwise, one might also choose an active placebo, treatment as usual (TAU), standard of care, active comparator, waiting list, and within each of these, variations.

Experience in RCTs suggests that whatever one decides as the appropriate control group, someone will see as the wrong choice. Some researchers, for example, feel strongly that every RCT must have an inert placebo group. Other researchers feel equally strongly that use of an inert placebo group is unethical when known effective treatments already exist, that, in those circumstances, a placebo control group is essentially withholding treatment from patients who need treatment. Some researchers are enthusiastic about a TAU control group since that would be the basis of conveying the message to clinicians that a new treatment T is better than what clinicians are currently generally using. Others point out that TAU would mean heterogeneity of treatments, differently and perhaps inadequately delivered, and no clear indication of which treatments T is better than. Many would prefer a standard of treatment delivered within the study protocol, but which one? Waiting list control also means that treatment is withheld for the duration of the study, but even more troubling, those randomly assigned to the waiting list often seek other treatments and drop out before the waiting period is over, creating major problems with attrition in the analysis. When an active comparator is used, if T ultimately proves preferable to C, that presents a clear message. But if not, whether the two are equally good or equally bad is not clear, in the absence of a separate placebo control group (Leon, 2011). Moreover, if T and C are here two competing drugs from two pharmaceutical companies, it is amazing how often studies conducted by the company producing T find T preferable to C, and vice versa (clinical equipoise?). The arguments go on.

Thus, generally the best one can do is to consider carefully the current situation with regard to T, and what message the study is intended to convey and to whom, and make the most thoughtful choice possible, but without any expectation that choice will avoid criticism.

Randomization

The simplest randomization method involves tossing a fair coin or die to assign each patient to T or C when that patient signs

the informed consent form. Every biostatistician, however, can relate some horror story where this was done, only to find, after the RCT was under way or done, that someone gerrymandered assignments. For example, in one RCT, the research assistant, charged with tossing the coin to determine treatment group, when faced with a seriously ill patient who, in his opinion, “really needed T,” simply flipped the coin again and again until it dictated assignment to T. After all, he argued, each coin toss was equally random, wasn’t it?

Problems stem from lack of “blindness” in recruiting and assigning the patients. When it is known or strongly suspected that the next patient is to be assigned to what the assigner considers a less preferred treatment, she/he can, consciously or not, delay that patient’s entry until the prospects are better. Such gerrymandering can be avoided by “blinding” the assigner. For example, one might perform the coin/die tosses *before* the study is started, placing each assignment in a numbered, sealed, envelope, which the assigner must label with the patient’s name upon entry to the study *before* opening the envelope. Since the assigner can only know the assignment *after* the patient is signed in on a numbered envelope (which can be checked), this reduces the chance of gerrymandering. Alternatively, a computer program can be set up, into which the patient’s identification is entered, upon which the computer delivers the random assignment.

Gerrymandering is only one problem. Another problem is balance. By balance we mean that the proportion of the sample assigned to T matches reasonably well with the proportion the design requires (often equal assignment to two groups). With simple randomization with equal probabilities, if the total sample size is 20, the probability that exactly half end in T is 0.18, and that probability *decreases* as the sample size increases. If the sample size were indeed only 20, there is some chance that the RCT will end with some very uneven split, say 15 in T and 5 in C. Drawing inferences from a sample as small as 5 is risky. If on the other hand, the sample size were 200, 105 in T and 95 in C, a similar imbalance, the situation would not be so uncomfortable because a sample size of 95 remains substantial. Thus, the balance problem is most important when dealing with relatively small sample sizes.

The traditional way of dealing with this problem is blocking. Blocks of 2, 4, 6, 8, and so on, are used with successive block sizes randomly varied within the trial, the size of blocks unknown to any of the researchers. Within each block exactly half are assigned to T, the other half to C. The larger the block, the better is the blinding, and thus the better protection against gerrymandering. At the end of each block, the sample sizes are exactly balanced. However, the larger the block, the more likely the recruitment will end inside a block, sometimes still leaving an unwelcome imbalance.

A better alternative is the Efron procedure (Efron, 1971). As each patient sequentially enters the RCT, the numbers previously assigned to T and C are tracked. If an even split is required, whenever the sample sizes to date are equal, the probability of assignment to T is 0.5. If, however, these numbers are unequal,

the probability of assignment to the minority group is slightly higher, say 2/3, and consequently that to the majority group slightly lower, say 1/3. This exerts a constant pressure to keep the group sizes near equal. Yet, it is difficult to predict where the next patient is likely to be assigned, preserving “blindness.”

Balancing is one issue, matching yet another. As noted earlier, randomization does not guarantee “matching” between the groups, but produces two random samples from the same population. Thus, the age, gender, initial severity, and so on, of the T and C groups that result would not be expected to have exactly the same means and variances. Many researchers are concerned that the occasional mismatch can compromise the interpretations of any group differences, and try to ensure better matching by a variety of methods including adaptive randomization.

Before considering such options, it should be noted that there are an almost infinite number of baseline variables, but most are irrelevant to treatment outcome. Matching the two groups on an irrelevant variable increases the difficulty of doing the RCT but has no effect on the credibility of conclusions, and may cost power. Moreover, the harder one strives to match groups on one set of baseline variables, the more likely the groups are to end mismatched on others. It all too frequently happens that the variables selected to match the groups are not the variables most important to the outcome, in which case, the results may be more seriously compromised using matching procedures than they would have been without.

In an adaptive randomization, the characteristics of the two groups on a list of crucial variables are tracked as patients enter into the study. If the two groups are matched on these variables, the probability of assignment to T is 0.5; if not, the probability is moved slightly toward assignment to whichever group would bring the characteristics into a better match. This then exerts pressure to keep the two treatment groups matched, at least on the variables selected to be considered.

There are a variety of other randomization tactics designed neither for blinding, balancing, or matching, but to deal with other practical problems often encountered. To take just one: equipoise randomization.

Often eligible patients being recruited to an RCT may not agree to randomization. If such patients are excluded, one may end with an unrepresentative sample from the population of interest. When there are only two treatments in the RCT (the focus so far), say T and C, this does not pose a major problem, for then the conclusions apply to those patients for whom the T versus C choice is possible. Since clinicians are ethically barred from treating patients with a treatment they will not accept, this limitation matters little. However, suppose there were more than two treatments, T1, T2, ... Tm?

Traditionally, using the same principle, one should exclude from randomization all patients who would not accept randomization to all m treatments. Quite aside from the fact that this may cause serious problems with access to sufficient sample size, it may also result in a very biased sample from the population of interest. The population, for example, would include many

patients who might agree to either T1 or T2, but they would be excluded because they would not agree to T3 or T4.

Equipoise randomization (Lavori *et al.*, 2001) requires that each patient be given the best argument for equipoise among all the m treatments in the informed consent process. If the patient will agree to randomization to at least two of the treatments, that patient is randomized to as many of the m treatments as she/he would accept. Thus, patients who would not accept T3 or T4, but would accept T1 and T2, are included in the sample. Then each pair of treatments is considered separately, on that subsample who would accept that choice and the conclusions from each analysis apply to those patients for whom that particular choice is acceptable.

Choice of outcome measure(s)

In an RCT, outcome measure(s) are specified “*a priori*,” should be registered and/or published before the trial is under way, and not modified thereafter (DeAngelis *et al.*, 2005). The question is: Which outcome measure(s)?

Any statistician worth his/her salt will recommend that every RCT have *one* primary outcome measure, and that the RCT be designed to have adequate power to detect T versus C differences on that *one* measure. Then if the RCT shows that there is a clinically significant advantage of T over C, that provides a clear message to clinicians.

Every clinician worth his/her salt will protest that having only one outcome measure can never capture the totality of effects on the patient that should influence clinical decisions between T and C. There are always multiple benefits (hastens remission, minimizes symptoms, improves quality of life, etc.) and multiple harms (increases risk of suicide, weight gain, headaches, etc.)

In response, the statistician will point out that if one tests multiple outcome measures, each with a 5% chance of a result indicating that T > C when there is no difference (a false-positive result), with 2 outcome measures there is a 10% chance, with 3 a 14% chance, with 10 a 40% chance, and so on. Including multiple outcome measures as the basis of clinical decision making proliferates false-positive results unless one adjusts the chance of a false positive so that the overall chance is less than 5%. However such an adjustment is made, it results in a loss of power to detect true treatment effects: the more numerous the outcome measures, the greater the loss of power. Moreover, on some outcomes T will be shown preferable to C, some have T clinically equivalent to C, and some have C preferable to T. What sense any clinician or patient can make of that mixture of recommendations is hard to fathom.

One solution to this problem is emerging: an integrated outcome measure (Kraemer & Frank, 2010; Kraemer *et al.*, 2011; Wallace *et al.*, 2013). The fundamental idea of an integrated outcome measure is that all independent outcome measures of clinical importance are first identified and well and carefully measured in the RCT. Then clinical judgment is used to weigh and balance the cumulative effects of these outcomes on the individual patients.

A simple example was the outcome proposed (but not so used exactly) in the CATIE study evaluating drug treatments for schizophrenia (Lieberman *et al.*, 2005). It was proposed that each patient be clinically tracked over time and the treatment be discontinued for either lack of efficacy or of tolerability based on the clinical judgment of the treating physician “blinded” to treatment. What constituted efficacy (reduction of symptoms, increase in functional status, increase in quality of life, etc.), and what constituted tolerability (increase in weight, tardive dyskinesia symptoms, etc.) and how one would balance one against the other, might vary from patient to patient, and perhaps from clinician to clinician. However, it was left to clinical judgment as to when the total impact of harms exceeded the total impact of benefits on each individual patient. The single outcome measure would be time to treatment failure.

Power and precision

Once all these decisions are made, each of which impacts the sample size, a decision needs to be made as to how large a sample size is needed for adequate power in testing and adequate precision in estimating effect sizes. The classical way is to propose “*a priori*” a significance level, usually 5%, that indicates the minimally acceptable risk of a false-positive result, and then to determine what sample size is needed to have an “*a priori*” level of power, typically 80%, to detect any effect size that would be considered of clinical significance, that is, an effect size greater than the critical effect size. This is the same as the necessary sample size in order that a 95% confidence interval for the effect size does not include zero when the true effect size is greater than the critical effect size, that is, adequate precision for estimation of the effect size. Thus, shifting from consideration of power for a statistical test is tantamount to consideration of precision for estimation of an effect size.

Every decision made, particularly those related to outcome measures, has an impact on the necessary sample size. As a general rule, an outcome measure that is very sensitive to crucial clinical individual differences in response to treatment will yield greater power in testing and greater precision in estimation with smaller sample sizes.

The weakest possible outcome measure is a binary measure: success/failure. For example, if “success” is defined as remission within 1 year, a patient who remits at 1 year + 1 day is considered tied with patients who remit at 2 years, 3 years, or never. A patient who remits at 1 year – 1 day is considered tied with patients who remit at 1 week, 1 month, or 6 months. To choose this outcome measure will require the largest possible sample size for adequate power/precision. The cost of dichotomized outcomes has long been recognized but often ignored (Cohen, 1983).

In this case, we might instead propose to use time to remission (an ordinal variable) as the outcome, and survival methods to test or to estimate an effect size (Kaplan & Meier, 1958). Now the

only patients who will be tied are those that remit at the same time, resulting in a major increase in power/precision. But two patients who both remit at the same time may differ radically in their course. One may have experienced a very rapid decrease in symptoms early but then drifted toward remission, while the other may have been highly symptomatic until just shortly before remission. Similarly, two patients may remit at the same time, but one remains symptomatic afterward, while the other completely recovers. Yet these pairs are tied in time to remission.

Instead, we might propose to use repeated measures over time of symptom level (those that define remission), and use a hierarchical linear model (Gibbons *et al.*, 1993) to compare the complete trajectories of response. Now we have an approach sensitive both to the timing of remission and to the course prior to and after remission. To do so will result in a further increase in power/precision, thus reducing the necessary sample size.

The key issues in selecting the outcome measure in an RCT is (a) to consider exactly what responses are crucial in deciding between T and C, no more or fewer than are necessary; (b) to guarantee the reliability and validity of these responses, and to assure maximum sensitivity to crucial individual differences in response among patients, preferably with repeated measures of each over the course of treatment; (c) if necessary, to combine multiple such measures reflecting their importance to clinical decision making. To do this not only increases how clinically informative the results but also increases power/precision and reduces the sample size and hence the difficulty and cost of doing RCTs.

RCT execution/fidelity

The greatest intellectual effort occurs in the process of designing an RCT. All that needs to be done during the RCT is to follow one’s own rules. That makes it all the more remarkable how often, once the RCT is under way, the researchers begin to drift from those rules. Inclusion/exclusion criteria become either stricter or looser, measurement procedures are modified, the number and timing of evaluations shifts, and so on. The consequence of any deviations from the original protocol is, at the very least, to introduce extraneous variability into the results, and thus to sacrifice power/precision. At the very most, the validity of the study to test the original hypothesis is compromised. Strict adherence to the research protocol, both in the delivery of the treatments, and in the conduct of the RCT is referred to as “fidelity.” Fidelity is often a focus of attention in multisite trials, to ensure that the sites do not end doing different RCTs, precluding combining the results from the different sites, testing generalizability of the results, or estimating a common effect size and its confidence interval. However, fidelity is equally important in a single site RCT. When a well-designed and adequately powered RCT fails, it is most likely due to lack of fidelity.

Primary analysis and presentation of results

In a well-conceived, well-designed RCT, the primary analyses are those specified ‘*a priori*’ on which the power calculations determining the sample size of the study were based. Table 1 in any RCT report generally provides descriptive statistics describing the baseline characteristics of the population as estimated in the sample. Often descriptive statistics are provided separately for the T and C groups to document that the randomization produced two similar samples (neither too badly nor too well matched). Often researchers will test the null hypothesis that randomization was done by testing T versus C differences on each baseline variable. This is a puzzling but harmless practice, since the researchers surely know with certainty whether they did or did not randomize!

However, as we’ve noted, with randomization to two groups, 5% of independent baseline variables should significantly differentiate the two groups at the 5% level. With replication, which variables do so, will vary. However, researchers often respond to finding such differences in an RCT by proposing to “control” these factors by including them as covariates when comparing T and C. Two problems then arise: (a) This is now “post hoc” analysis since the hypothesis being tested was generated by looking at the data to be used in testing that hypothesis and is different from the one originally proposed. (b) Since the variables chosen are those correlated with treatment choice, collinearity is introduced. Both compromise the validity of the testing and estimation. The test done to address the primary research question in the RCT report should still be the analysis proposed “*a priori*.” The CONSORT guidelines (Schulz *et al.*, 2010) provide excellent information on what information needs to be reported from an RCT.

However, after that analysis produces whatever results it does, it would be appropriate, on an exploratory level, to ask whether any baseline variables (whether well matched in the two groups or not) are either nonspecific predictors or moderators of treatment response, with emphasis on effect sizes and their confidence interval, not on statistical tests. If important relationships are thus detected, these findings are then checked against existing literature, and if now there is rationale and justification for hypothesizing a nonspecific predictor or a moderator, this hypothesis would be tested in a *subsequent independent* RCT, with a design better suited to detection of such relationships.

Moving the frontiers: exploration of RCT data

The completion of the primary analysis “as intended” is not the end of the project. There are at least three important strategies that should now be implemented: (a) continued education in RCT methodology; (b) checking the internal validity of the study conclusions; (c) exploratory (hypothesis-generating) studies to

set the stage for furthering and deepening the understanding of the results of this RCT, particularly efforts to identify moderators and mediators of treatment response.

There has probably never been an RCT done, that upon completion, the researchers involved could not look back and identify actions they should have taken but did not, actions they did take but need or should not have, actions that might have been improved. Conscious consideration of these actions, a sort of statistical autopsy, is an excellent form of continued education, the less than perfect decisions in one RCT leading to improved methodology in the next. Moreover, it is the investigators’ responsibility to identify and to report any challenges they know of to the validity of their findings (internal validity). Statistical autopsy facilitates this process.

Finally, considerable effort should be invested in trying to discover the moderators and mediators of treatment response (Kraemer *et al.*, 2005). A *moderator* of treatment response is a baseline (prerandomization) factor that identifies subgroups of patients within the population sampled who have different effect sizes. Thus, to take a simple example, gender moderates the effect of treatment if the effect size comparing T versus C is different for boys than for girls. In most cases, unrecognized moderators deflate the overall effect size. Indeed, it is possible that the primary analysis demonstrates a zero effect size, but that for girls the effect size is large and positive and for boys large and negative, thus canceling each other out.

Moderators are important since generally no T is uniformly better than C for all in a heterogeneous population. However, without the means to identify which patients would profit more from T and which from C, patients will often be given a treatment ineffective and even sometimes dangerous for them, only because they happen to be in a minority where the majority finds the treatment effective and safe. In recent years, emphasis has been placed on personalized medicine (Jain, 2002; Lesko, 2007), efforts to move past this “one size fits all” philosophy.

A *mediator* of treatment response is an event or change that occurs early in treatment before outcome is determined, that differentiates T from C, and that explains some or all of the overall effect size comparing T and C in the population sampled. For example, it may be that a systematic drug treatment (T) for ADHD when compared with TAU leads to an early change in parenting behavior, and that the subsequent change in symptoms posttreatment reflects both the direct pharmacological effect as well as the effect on parenting. In this case, the change in parenting behavior mediates the treatment choice on change in symptoms.

While moderators are important to assigning each patient whichever of T or C is likely to be preferable for him/her, mediators are important to understanding the process by which T produces its effect. Where there are moderators, mediators may be different in subgroups defined by the moderators. Thus, for example, if gender moderates treatment response,

the mediators of treatment response may be different for boys and girls. Logically then, the exploration for moderators should precede the exploration for mediators.

Mediators are important to considerations of how treatment might be improved. Finding that the change in parent behavior was a mediator of a drug treatment might suggest either adding components to the drug treatment to amplify this effect on parent behavior, or considering whether focusing on strategies to change parent behavior in absence of the drug treatment might be just as effective, or developing strategies for somehow tying drug dosage decisions to observations of parent behavior.

When moderators and mediators are detected in exploratory analyses post RCT, these are hypotheses to be tested in future independent studies, not conclusions. Considering the sheer number of baseline variables, and the number of different events or changes that might occur early in treatment, such exploratory analysis will generate many false-positive results. Consequently, any potentially important moderation or mediation so detected must first be supported by rationale and justification in the existing literature, and then formally tested in a *new* RCT designed for the purpose.

Completing the cycle: meta-analysis

No single research study ever establishes a scientific fact. That always requires independent validation, either a replication or another study that validates the conclusion. The best method available to establish consensus in multiple studies addressing the same T versus C comparison is meta-analysis.

It is the responsibility of the meta-analyst to identify inclusion/exclusion criteria for the studies to be included. For example, if there are both RCTs and observational studies comparing T versus C, should both be included? If one study samples only women and another a mixed-sex population, should both be included? As inclusion/exclusion criteria for patients in an RCT determine the conclusions to be drawn, so also do the inclusion/exclusion criteria for studies in a meta-analysis determine the conclusions to be drawn there.

Then one effect size from each study (and some measure of the precision of its estimation) is taken from each study, and these effect sizes are tested for homogeneity (i.e., consensus). In the absence of heterogeneity, the effect sizes are then pooled and the confidence interval of the pooled effect size estimated.

There are nine possible configurations of an RCT or a meta-analysis of RCTs (Figure 14.2). If the null effect size is not included in the confidence interval, the result is “statistically significant at the 5% level.” Thus, #1,2,3 are all “statistically significant”; #4,5,6 are not. If only effect sizes greater than the critical effect size are included, the result is “clinically significant.” If only effect sizes less than the critical effect size are included, the treatments are “clinically equivalent.” Thus, #1 shows two

Figure 14.2 Ninety-five percent two-tailed confidence intervals on the effect size comparing T versus C showing the nine possible patterns that might result, where SRD* is the critical effect size.

results (in opposite directions) where the RCT demonstrated both statistical and clinical significance. #2 shows two results where there was statistical significance, but clinical significance remains in doubt, suggesting the necessity for further studies. #3 and #4 both show clinical equivalence, but #3 is statistically significant and #4 is not. #5,6 show failed studies, that is, before these studies, with clinical equipoise, it was not known which of T and C were better, and if so whether the difference was clinically significant. Here, after the studies, no more is known than was known with clinical equipoise before the studies.

After meta-analysis, #1, #3, #4 are conclusive results—consensus has been reached. #2 is promising but not conclusive, perhaps requiring more studies. However, #5,6, would indicate a waste of patient time and effort, time, and resources, for the process of comparing T versus C has not yet truly started.

If the studies included in meta-analysis are all valid and adequately powered to test the same T versus C in the same population on the same outcome, some 3–5 studies in a meta-analysis will likely be conclusive. If, on the other hand, only valid studies but many inadequately powered are included, it may take 10–20 studies to be conclusive. But if the inclusion/exclusion criteria for the meta-analysis are loose enough to include different populations, different outcomes, different versions of T or of C, or studies are included that are not valid, establishing consensus may be an impossible task.

It is not unusual to hear researchers justify a badly designed underpowered study (often erroneously called a “pilot study”) by claiming that in itself, such a study may not lead to closure, but in combination with other studies, makes a contribution. Including such studies in meta-analysis not only encourages future such poor studies, but is likely to slow the research process leading to consensus. It is important that meta-analysts do a very complete survey of all studies done on an issue, but they should base their conclusions only on studies that, in their estimation, are both valid and adequately powered.

Discussion

How evaluation of treatment was done in the early 20th century was very different from that in the late, when RCT methodology was introduced and disseminated, and the changes continue. The advent and development of survival methods, the introduction of hierarchical linear models, the development of meta-analysis methods, the recognition of the importance of moderators and mediators of treatment response, and many such methodological advances, changes the way treatments are evaluated. Emphasis on presenting effect sizes and their confidence intervals in addition to p values changes the way results are reported. Changes affect not only analysis of results, but the decision on how and whom to sample, how to design the RCT for maximal validity and power, what outcome measures to use, and so on. The process of change will undoubtedly continue, bringing clinical trials ever closer to realizing the goals of clearly informing clinical decision making.

CHAPTER 15

What clinicians need to know about statistical issues and methods

Andrew Pickles and Rachael Bedford

Department of Biostatistics, Institute of Psychiatry, Psychology and Neuroscience, King's College London, UK

Although as an academic discipline statistics is often associated with mathematics, it has had from its beginnings strong links to science—both in application and in the stimulus for new methodological development. The rationale for the use of statistics is as an objective and efficient operationalization of the scientific method in a context of complex data. Statistical methods should be achieving these aims in several ways: firstly, by requiring precise operational definitions of theories and explicitly specified critical differences or contrasts; secondly, by providing methodology for estimating scientifically meaningful quantities as precisely as possible and freed from as many sources of bias as possible; thirdly, by providing a framework for determining how uncertain our estimates are and whether data are consistent or inconsistent with theory. Some introductory statistics classes and books give the impression that statistics is more concerned with making assumptions; assumptions that appear abstract, derived from probability theory, with little meaning and anyway probably rarely met in practice. This is unfortunate, since in the majority of cases the assumptions correspond to critical scientific simplifications of a kind that most scientists and clinicians could easily comprehend and would have considerable intuition as to whether they are likely to be met or not. Moreover, it is crucial for the quality of the science that it be understood that such assumptions are being made.

For many years there has been a division of approach into experimental and observational/epidemiological studies. Experiments are often seen as strong for determining causation but having weak generalizability, while observational studies are seen as weak on causation but strong on generalization. While trivially apparent from the frequent use of analysis of variance for experiments and regression for observational studies, more profound differences exist. The first, traditionally given great emphasis, is the exploitation of randomization within experiments. The second is the careful pre-specification preceding an

experiment. Such differences are amplified by the context of any statistical analysis. In clinical trials of pharmaceutical drugs, the massive financial interest makes the primary role of a statistician a “defensive” one, to prevent false claims of efficacy. In contrast, academic psychology has been more exploratory and theory confirming. Thus, what statistical analysis might be recommended will depend on much more than many introductory texts suggest.

Common misunderstandings, study design, multiple testing, meta-analysis and the natural history of “findings”

There is a common natural history for many “findings.” First a small study finds a significant association and persuades an editor of its value. Many small studies fail to replicate the finding, but since everyone knows that small studies have “low power” this comes as no surprise; few, if any, such findings are published. Any small replication studies that do find a significant association are published, apparently confirming the interesting finding. Eventually, a large study fails to replicate the finding, and because of the study’s size and the fact this failure is now seen as overturning a received wisdom, the results are published in a prominent journal. Patients then need to be persuaded that something formerly considered effective is now considered ineffective. How does this come about?

One key issue concerns the fact that readers and editors of papers are drawn to reports of significant associations rather than reports of non-significant effects. As a consequence, the p value remains the statistic upon which the success or failure of a study is seen to rest. Every study, regardless of size, has a fixed chance of identifying a significant effect in the sample drawn when there is no such effect in the population. Known as the

Rutter's Child and Adolescent Psychiatry, Sixth Edition.

type 1 error, we usually set this risk as 1 in 20, or 0.05. If we test for the presence of two effects or study the same effect in two samples, then the risk that at least one of these might show a significant finding is now slightly less than 1 in 10. Test for the presence of enough effects or carry out enough studies and some are bound to be falsely significant. This is just the problem that geneticists face when testing for significant associations between a particular disorder and hundreds of thousands of gene single nucleotide polymorphisms (SNPs) or neuroimagers with similar numbers of brain features. The Bonferroni correction can be used to set a meaningful significance criterion when the effects being tested are independent, or alternatively tests can be applied that account for the correlation, for example, permutation and false discovery rate tests (Benjamini & Hochberg, 1995).

Rather than significance, statisticians argue that it is the size of the effect or difference, together with some measure of precision, preferably a confidence interval (CI) that should be reported. The CI gives the opportunity to reflect upon the range of possible values that can be considered as potentially consistent with the data and to assess whether effects of this magnitude would be, say, of clinical importance.

Sample size also needs to be considered when assessing the likely importance of significant effects. It is a common misconception that finding a significant effect in a small study must mean that the effect is substantial. In small studies, the magnitude of the estimate must be large for it to appear as significant—in a small study, all small effect estimates are non significant—and just because the estimate is large does not mean that the true effect is necessarily so. Although both large and small studies have the same chance of falsely identifying one of the many “no-effect” factors as significant (false positive), larger studies have greater power to detect the few true-effect factors as significant. Thus, of the effects found to be significant, a higher proportion of those from a small study will be false and of an exaggerated size as compared to the proportion from a large study.

This is one of the problems that meta-analysis, also known as systematic review, attempts to overcome (Cooper *et al.*, 2009). A systematic review usually consists of four steps. First, assembling an exhaustive list of the potentially relevant published studies; second, selecting against a predefined list of criteria a subset whose design, implementation and clarity of reporting suggest that they are appropriate and of good quality. Where possible this second step should be done blind to authorship and to the actual findings of the study. The third step is to display the findings of these studies in a funnel plot (Light & Pillemer, 1984). Figure 15.1 shows data from several acupuncture studies illustrating the diminution of effect size reported as the sample size increases, to the point where the largest study shows no effect. If the true effect is zero, then the figure also shows evidence of publication bias, since if all little studies were published one would expect their estimates to be scattered symmetrically around the larger studies. Such evidence of publication bias

Figure 15.1 Funnel plot showing clear evidence of publication bias. *Source:* From Tang *et al.* (1999). Reproduced with permission of BMJ.

should prompt significant concern and a search for unpublished studies. The final and most technical step in a systematic review is the method used to pool the information to come up with a single overall estimate of the average effect.

A focus on significance, sample size and publication bias are not the only reasons for the natural history of findings with which we began this section. In addition, although there are important exceptions, because large projects cost more and are commonly staffed by more experienced researchers, they tend to be superior on a whole range of methodological measures of quality, such as being prospective rather than retrospective, having blind assessments and being better analyzed and reported. Each of these factors tends to exclude possible biases that can contribute to artifact. Indeed reported effect size does seem to decline as the methodological rigor of the study increases (Schulz *et al.*, 1995).

More recently, some apparently robust findings from epidemiology have been tested in randomized trials, considered by most as the ultimate study design for testing causal effects (see Chapter 14). Results from several high-profile treatments have been not just disappointing, but in the case of hormone replacement therapy (HRT), in contrast to the beneficial effects reported from epidemiological studies (Petitti *et al.*, 1986) the trial finding actually suggested it to be dangerous (Hulley *et al.*, 1998).

A possible explanation for the discrepancy between trials and observational studies may lie in inadequate control of factors such as socioeconomic position (Lawlor *et al.*, 2004). Others have suggested that the discrepancy is resolved if the formal attention to detail in specifying eligibility, treatment and outcome that characterizes an RCT is applied to the epidemiological data (Hernán *et al.*, 2008). Such a proposal, for greater care, clarity and objectivity in the analysis of epidemiological

data, we believe to be important and of wide relevance (see Chapters 12 and 14).

Confounding, selection and randomization

Rarely is an outcome of psychiatric interest related to just a single causal factor. In practice, many different processes are and have been at work to give rise to the current mental state of an individual. Moreover, many of the factors of interest in child psychiatry co-occur. Poor families tend to live in poor neighborhoods, with poor educational opportunities and suffer psychosocial risks and stresses that give rise to discord. Thus, a group of children identified by any one of these factors will have an unusually high frequency of the other factors. There are two important aspects of this problem. The first, “independent effects of confounders,” relates to the fact that these other factors may have effects which we should attempt to account for. The second, “selection effects,” refers to the variation among subjects in their exposure to the factor of interest being correlated with variation in these other factors. In other words, those who are selected to be exposed to one risk factor have commonly experienced and are experiencing these other risks as well. The effect of our factor of interest will be confounded with the effects of these other risks. Broadly speaking, we can attempt to solve our problem if we can deal with either of the two aspects of the problem.

Adjustment for measured confounders: regression and the generalized linear model

One way of dealing with confounding is through standardization, for example, standardizing intelligence scores to remove the effects of age. A large calibration sample is used to translate a raw score into a standardized score that measures the extent of deviation from the norm for a particular raw score at a particular age. Standardization can also take the form of weighting age-specific sample data to correspond to a population with a standard age distribution. However, adjustment for variables about which we know rather less, especially when we have several of them, requires a more generic approach, typically provided by some form of regression model. For continuous outcome measures the familiar regression model is used to combine the effects of several factors. In this model, the expected value of the outcome Y is assumed to be some linear combination of the predictor variables (X_1 and X_2):

$$E(Y) = \alpha + \beta_1 X_1 + \beta_2 X_2$$

and the variance of the outcome around its expected value is assumed to be constant (homoscedasticity). No assumptions are made about the distribution of the X variables, they can be continuous or discrete (binary dummy categorical variables).

Of course, there are many outcomes for which this linear model is not appropriate, and we then often turn to some form

of the generalized linear model (GLM; McCullagh & Nelder, 1989). This allows two extensions to the ordinary regression model. Firstly, a choice of link function which transforms the expected value of the response. For example, for a count response a log link would be chosen:

$$\log[E(Y)] = \alpha + \beta_1 X_1 + \beta_2 X_2.$$

This would ensure that all predicted counts are positive. Secondly, a different distribution for the variability of the observed response can be chosen. The key feature of this choice is how the variability in the observed responses might be expected to increase with its expected value. For example, in ordinary regression, no increase is expected while with a Poisson distribution the variance increases with the mean. Poisson regression is often used with count outcomes.

The other commonly used GLM is the logistic regression model suitable for analyzing binary outcomes. This model estimates odds ratios (ORs), a measure of effect that has both desirable and undesirable properties. Desirable is that it is the only measure of association between risk factor and binary outcome that is unaffected by over-sampling risk exposed or by over-sampling outcome cases (but not both at the same time). Thus the odds ratio estimate from a cohort study and a case-control study should be the same. Unfortunately, most readers and, worse still, many authors interpret the odds ratio as a risk ratio, which in psychiatry it approximates only rarely. For example, an odds ratio of 2 does not imply a doubling of the rate unless the outcome is very rare. If the rate in the unexposed group is 2%, then the rate in the risk group does indeed double to $(2 * 0.02/0.98)/(1 + (2 * 0.02/0.98)) = 4\%$. However, with an unexposed group rate of 20%, an OR = 2 implies a rate in the risk group not of 40% but of $(2 * 0.2/0.8)/(1 + (2 * 0.2/0.8)) = 33\%$, and with an unexposed group rate of 80%, then an OR = 2 implies a rate of $(2 * 0.8/0.2)/(1 + (2 * 0.8/0.2)) = 89\%$ in the risk group.

Regression and the more general GLM make adjustment for several covariates straightforward. It is therefore widely applied. However, it should not be considered as a cure-all and should always be accompanied by careful thinking through of the assumptions. A typical example is shown in Figure 15.2 for 167 children from a prospective study of autism (Lord *et al.*, 2006). Initial verbal IQ is associated with initial diagnosis using an observation-based assessment, the Autism Diagnostic Observation Schedule (ADOS; Lord *et al.*, 2000). Verbal IQ significantly relates to autism and autistic spectrum diagnosis but not to pervasive developmental disorder not-otherwise-specified (PDD-NOS) or non autistic spectrum (NS). We might wish to examine how diagnosis made at age 2 is associated with ADOS social-communication score at age 9, taking into account initial verbal IQ. We could do this by covariate adjustment for verbal IQ in an ANOVA where age 2 diagnosis was a between-subjects factor, or equivalently by including both diagnosis and verbal IQ as main effects in a regression. We would obtain the

Figure 15.2 Distribution of baseline verbal IQ and diagnostic groups (PDD-NOS = autistic spectrum but not autism).

answer that compared to those initially diagnosed with autism, the PDD-NOS (-2.52 ; 95% CI $-4.69, -0.35$) and NS (-4.59 ; 95% CI $-7.20, -1.97$) groups score lower on the ADOS at age 9, with each additional verbal IQ point associated with a 0.102 (95% CI $0.144, 0.062$) lower ADOS score. But what have we assumed in this adjustment process? We focus here on the assumption of linearity, both within and between groups, which has allowed us to make an adjustment across the whole range of IQ in the sample. A cursory examination of Figure 15.2 shows that most children (71%) with an initial diagnosis of autism have a verbal IQ below that of the child with the lowest verbal IQ in the NS group. Were we to control for verbal IQ by matching, a non parametric approach that does not assume linearity, these children with autism and low verbal IQ would find no match in the NS group and would be dropped from the analysis. We could restrict our covariance adjustment to the verbal IQ range shared by all three diagnostic groups. The resulting analysis of 78 (previously 167) children gives estimates of outcome differences of -0.92 (CI $-4.09, 2.26$) and -3.94 (CI $-7.37, -0.50$), for PDD-NOS and NS respectively, which are smaller and much less precise than the previous estimates. The covariance adjustment using the whole sample may be more powerful, but that power was gained at the expense of a more speculative assumption that the verbal IQ adjustment is correct even though in some areas of the scale the adjustment is being determined solely by children from one diagnostic group.

All these analyses have assumed that the way in which verbal IQ affects outcome is the same within each diagnostic group. Figure 15.3 shows the estimated relationship for each group, obtained from fitting a model that allowed an interaction term between diagnostic group and verbal IQ. Although this term was non significant ($F(2, 161) = 1.65$ $p = 0.2$), the figure clearly shows non parallel lines. These imply that the difference in ADOS outcome score depends upon the child's initial verbal IQ, and that the answer obtained from "adjustment" for verbal IQ may represent some sort of average difference that could hide important variation. Unless designed in advance, for example,

Figure 15.3 Relationship between baseline verbal IQ and follow-up ADOS score by initial diagnosis (NS = non autism spectrum; PDD-NOS = autistic spectrum but not autism).

by selecting subjects matched on verbal IQ, most studies do not have the power to test effectively for such variation. Unfortunately, designing a study to be powerful in this regard would make it clumsier to analyse for all but the designed contrasts. Moreover, the design would have increased power only with respect to the matched variables, and would exclude important sub-groups of children, in this case the majority of autistic children with low verbal IQs.

There remains the more general question as to what are relevant and suitable control variables. This is not a simple question. Understanding why autism and low verbal IQ are commonly associated, that is whether low verbal IQ increases false-positive autism diagnosis using current instruments, or actually increases risk of autism, or whether autism increases the risk of low verbal IQ, will be important for interpreting results and for deciding whether one should adjust at all.

Mechanisms and statistical interactions and effects scales

The term interaction has distinct substantive and statistical definitions. Since these usually relate to quite different concepts and each may be poorly defined in any particular instance, there is scope for much debate, mostly fruitless. The notion of synergy is often associated with interaction, where risk factors have worse effects when they occur together than when each occurs by itself. The concept may be of special importance within psychiatry where many of the features that are studied as being risk factors may in fact confer risk only in certain contexts. For example, we cannot say that childhood antisocial behavior is universally increased as a result of (1) divorce, since it may be beneficial if the absenting father is antisocial (Jaffee *et al.*, 2003) or (2) high levels of testosterone, since while its association with leadership may confer risk in neighborhoods where deviant peers are common, elsewhere its role may be related to socially valued characteristics (Rowe *et al.*, 2004).

Indeed, many behavioral responses may be adaptive or maladaptive depending upon the context. This makes resolving the confusion over interaction all the more pressing.

Where the response variable is continuous, relatively little confusion arises. Thus, as in Figure 15.3, slopes that characterize the relationship of one risk measure to an outcome score may be different in one group compared to another, and this slope variation can be tested for by a test of the interaction term. A group that has a particularly steep slope would be indicative of a form of synergy, though how it was described might also depend upon where the mean levels for the groups lay. More problematic is the circumstance where the outcome is a binary diagnosis or the occurrence of an event. Rothman (1976; Rothman & Greenland, 1986) describes how for causal factors that are relatively uncommon and where no synergism occurs, the combined effect of exposure to two risk factors should be additive. Where synergism occurs, for example, when one factor increases the risk of an individual being in a state of vulnerability, and exposure to the second risk factor increases the risk of occurrence of the final outcome of interest (a two-stage model—cf. Pickles, 1993), then the risk factors will appear to act multiplicatively.

For analyzing binary outcomes, the common models are the log-rate models of survival analysis and the logit model. The routinely applied logistic regression model has many desirable statistical properties, but few users appreciate that in most applications where the pathological outcome is not the majority, this model has closer correspondence to the multiplicative combination of effects (Pickles & De Stavola, 2007). Thus, it may not be appropriate for analyzing additive relationships. Additive main effects on these log-rate and logit scales imply multiplicative effects on the simple rate scale. For these models, the absence of an interaction can be consistent with synergy, and a significant (negative) interaction consistent with no synergy. Simply put, there is no correspondence between the need for a statistical interaction and synergy, since the former depends upon the scale in which the main effects have been combined (Blot & Day, 1979).

Our task should be to fit a parsimonious but adequately fitting model with easily understood and well-behaved parameters, which the logit model is, but then to support the interpretation, particularly the public health interpretation, by examining group-wise predicted outcome rates (see Pickles & De Stavola, 2007).

In treatment research, synergy is referred to as treatment effect moderation. To some extent, research into moderation has been slowed because in RCTs statisticians have regarded it with suspicion, as opening the door to sub-group analysis. Where no overall effect has been found, proponents of a therapy commonly attempt to salvage something by fishing for groups of patients for whom it did appear to work, and doing so with neither the necessary power nor corrections for multiple testing. The more recent enthusiasm for *stratified* or *personalized* medicine has required statisticians to be more sympathetic, for example,

suggesting ways for constructing indices of moderation from a collection of potential moderating variables (Kraemer *et al.*, 2002; Wallace *et al.*, 2013). For psychological therapies, some theoretically important variables, such as the alliance between therapist and patient, are thought to be important moderators of the effect of therapy. However, they represent a substantial statistical challenge as these occur after randomization. Sound methods for such variables are under development (Dunn & Bental, 2007; Dunn *et al.*, 2013).

Longitudinal data analysis

Longitudinal data arise from repeated observations on one or more variables over time. The nature of this repeated measurement of data makes it expensive to collect both in terms of the number of measurements (at least two for each participant) and the cost of tracking participants over time. However, for addressing questions in development, longitudinal data provide the only real way to examine change over time. Unlike cross-sectional data, which allow only within-time correlations to be examined, longitudinal data enable the ordering of correlations over time to be assessed and thus come closer to addressing questions of causality.

One important issue when thinking about change over time relates to how “change” is measured. One approach is to calculate a simple difference score between time 1 (T1) and time 2 (T2). For example, if we want to look at change in language scores in males and females, we could compute a difference score for both groups separately and compare them. In psychology this is often called an *unconditional analysis*, and it compares the mean change in language scores. Another approach to the question of analyzing change over time is *conditional analysis* or *analysis of covariance* (ANCOVA), in which T2 language scores are regressed on T1 scores and, typically, a dummy variable for group. This answers the slightly different question of whether, given the same initial language score, the groups have the same expected increase in language scores by T2. ANCOVA allows for regression toward the mean, a term that describes the tendency of the scores of initially high (low) scoring individuals to fall back (rise up) toward the mean of the whole sample. However, ANCOVA assumes that this tendency is shared equally by all groups in the analysis, but evidence is rarely presented to support this assumption. Where groups are formed by random assignment, as in an RCT, this assumption would be expected to hold and ANCOVA is generally recommended as it is more efficient than the change score approach. In other contexts, while the change score might be preferred, some comfort is usually obtained by doing both analyses.

These approaches relate to measuring change for groups, rather than individuals. For small groups and for individuals in particular, it is common for most change in recorded scores to be the result of different measurement errors at the two occasions, a topic to which we now turn.

Measurement error, latent variables and growth models

Psychiatry is one of the few areas of medicine that takes measurement error seriously. Nonetheless, intuitive understanding of its impact on analysis is rarely well developed. Many researchers are familiar with the idea that if a risk factor is measured with error, then in any bivariate regression type model where the measure is used to predict an outcome, the estimated coefficient will be “attenuated” that is, the coefficient magnitude will be lower than if the risk factor had been perfectly measured. It is assumed that this simple attenuation effect carries over to more general settings involving several predictors. In fact, in more practical settings where there are several possibly correlated exposures, with one or more measured with error, such errors can have far more pernicious effects. Measurement error can readily be dealt with in a structural equation modeling framework, which we illustrate with an extended example.

Structural equation modelling

The application of SEM techniques to sociological research questions (Simon, 1954; Blalock, 1964) began over 50 years ago. SEM is a type of multivariate data analysis which can include both observed and latent (unobserved) variables. What a structural equation model is doing, in essence, is dividing the pattern of a variance–covariance matrix among the relationships specified in the model. These relationships can be among the observed variables, among the latent variables and between observed and latent variables (see Figure 15.4 for SEM notation).

The most basic building block of a structural equation model is a regression equation where the error, “e,” represents the disagreement between the data and the model, that is, data – model = error. The modelling approach involves both estimating parameters in the model, and assessing the model “goodness of fit,” that is, how well the proposed model recreates the variance–covariance structure observed in the data.

Ability scores (percentage of items correct) were collected in 6-, 7-, 9- and 11-year-olds (see Table 15.1) to measure continuity in general ability (Osbourne & Suddick, 1972).

Table 15.1 Summary statistics for the repeated measures of childhood ability (Osbourne & Suddick, 1972).

Age at measurement (years)	6	7	9	11
Mean cognitive ability	18.03	25.82	35.26	46.59
Standard deviation	6.37	7.32	7.80	10.39
Correlation matrix		0.809	0.806	0.765
			0.850	0.831
				0.867

A plausible starting model is the first-order autoregressive model (Figure 15.5) where ability at one age, having taken into account ability at the previous measurements, is not associated with any earlier measure. In such a model, an early measure may influence a later measure but only through an intermediate measure. The model consists of three regressions (Y1 on Y2, Y2 on Y3 and Y3 on Y4). In addition to estimating standardized regression coefficients (0.809, 0.850 and 0.867, respectively), as one would do in standard regression modelling, we can assess the model’s goodness-of-fit by comparing the observed and expected covariance matrix, from which we would conclude that the autoregressive model had a very poor fit (χ^2 statistic of 61.82 with 3 degrees of freedom¹). Something is wrong, but what? For many researchers the instinct is to conclude that additional relationships must exist, for example, from Y1 to Y3 and Y2 to Y4. These additional relationships correspond to “sleeper effects,” which have no effect on the immediately adjacent measure but yet can influence a subsequent one. There are circumstances where sleeper effects are plausible, for example, if items on a maths test for 7-, 8-, 9-, and 10-year-olds vary in content, with tests at two nonadjacent time points, that is, 7 and 9 years, more similar to one another than those at adjacent time points, that is 7 and 8 years.

¹ The degrees of freedom are found from the difference between the 10 observed summary statistics and the seven estimated parameters which are the variances for Y1, E2, E3 and E4 and the three regression coefficients b1, b2 and b3.

	Observed variable
	Latent factor
	Effect of one variable on another (e.g., regression)
	Covariance or correlation

Figure 15.4 Notation for structural equation models.

Figure 15.5 An autoregressive model for continuity. Y1–Y4 are observed variables, b_1 – b_3 are regression coefficients, E2–E4 are the residual error terms.

However, before adding additional pathways we should first take the issue of measurement error seriously. In the classical measurement error model, the observed measurement is additively related to a “true variable” F and a measurement error E of constant variance:

$$Y = F + E.$$

We can construct another type of autoregressive model with paths between latent variables, which represent “true” scores, to which the observed measures are related by the addition of measurement error (“ E ” see Figure 15.6). In order for the model to be estimated, certain constraints, such as, that the measurement error variance remains the same over the four occasions, are required. Though more complex, after imposing these constraints the model involves only one more parameter than the previous model (three regression coefficients between the factors and variances for F_1 , D_2 , D_3 , D_4 and the single common measurement error variance for the E s) and yet fits the ability data much better ($\chi^2 = 1.43$ with 2df). Clearly this model has no need of any additional sleeper effect, since it already fits so well. How has this come about? Variability consists of both measurement error and true score variance, of which only the latter can be expected to persist. Thus, in focussing on the apparent continuity in the total variation of a measure, the autoregressive model of Figure 15.5 underestimates the persistence of the true score, and thus the beta coefficients. This underestimation is even greater for temporally distant measures. The continuity

Figure 15.6 A latent variable continuity model. Y1–Y4 are observed variables and E1–E4 are the measurement error terms; F1–F4 are latent variables indicated by the observed variables and D1–D3 are the disturbances or factor residual error terms.

from Y1 to Y4 is given by the product of the standardized regression coefficients b_1 , b_2 and b_3 (a 10% underestimation in each coefficient resulting in a $1 - 0.9 * 0.9 * 0.9 = 27\%$ underestimation of the $b_1 * b_2 * b_3$ product). Allowing for measurement error corrects each regression coefficient and in so doing removes the gross under-estimation of the model-predicted long-term association.

There are numerous implications from this modest example. The first is that, in general, although measurement error in a covariate X_1 may result in systematic underestimation of its relationship with some response, it can also give rise to overestimation of the effects of some other covariate, X_2 , with which X_1 is correlated. Consider the often-repeated finding that current health is not only associated with contemporaneous risk factors but also independently with the same risk factors earlier in childhood. Is this because the risk has its effect through an accumulation of risk exposure, or is it an artifact of measurement error in the contemporaneous or childhood measurements? This latter possibility is rarely properly explored.

A natural alternative model for longitudinal data is a growth curve model in which each child is considered as having a trajectory defined by an initial ability, represented by a latent intercept factor—or random effect— F_1 , and a latent rate of improvement, represented by a latent slope factor—or random coefficient— F_2 (Figures 15.7 and 15.8). The intercept factor “loads,” that is, regresses, on all four measurements with a common regression coefficient. The growth or slope factor typically loads on all but the first measurement, with either distinct factor loadings on each path or with constraints such that the loadings vary in proportion with the time since the initial measurement (equivalent to allowing for the linear effects of time to be random). In almost all growth situations, values at the initial starting point are correlated with subsequent growth (i.e. the double-headed arrow linking intercept and slope in Figure 15.7), requiring the two latent factors or random effects to be correlated. Again we can impose restrictions such that the

Figure 15.7 Growth curve model with intercept and slope factors or random effects. Y1–Y4 are the observed variables and E1–E4 are the associated error terms. F1 is a latent variable for the random intercept and F2 is the random slope factor.

Figure 15.8 Regression line. Thick black line represents typical fixed effects regression line, the thin black lines represent spread of slopes implied by a random intercept factor (F1) and the dashed lines the spread of slopes implied by a random slope factor (F2).

measurement error variances (E1–E4) are constant. This model has one fewer parameter than the model of Figure 15.6 and yet fits these data better ($\chi^2 = 0.92$ with 3df).

Which of the two well-fitting models (Figures 15.6 and 15.7) should we choose? In this case, the choice is likely to rest upon theoretical considerations. The last model has the fewer parameters and in addition has the advantage of cleanly partitioning initial cross-sectional variation from subsequent change. This has appeal, especially were the model extended to allow for the effects of exposures to be associated with both the intercept and slope factors. Where continuous growth or decline are not expected, but instead change may be reversible, then random coefficients can be extended to a quadratic in time (or still higher order terms).

SEM with continuous and discrete variables and interactions: trajectory models

Much theory relates to groups or a categorical typology of individuals. A classic example is Moffitt's (1993) three anti-social behavior groups defined in terms of their longitudinal trajectory; life-course persistent, adolescent limited and never anti-social. Empirically defining these groups may be somewhat arbitrary, so a method that would identify them directly from the data with only general guidance from the researcher is desirable. These ideas may be operationalized within a trajectory model, a form of growth curve model in which the variation in the possible values of the intercept and growth coefficients are restricted to belong, in this case, to just 3 sets of values or "classes." Such a model can be considered as a form of latent class model or a model-based cluster analysis (Curran & Husong, 2003). We can compare the relative fit of a model with 2 or

4, rather than 3 classes to assess how gross an approximation the restriction to just 3 classes might be. It should not, however, be considered as a tool to identify how many classes actually exist. Two things argue against this. Firstly, the number of classes found as providing the best fit according to some standard information criterion (e.g. Bayesian or Akaike information criteria) varies with the extent of the data available. Secondly, although one can continue to add more classes, both theory and practice (Laird, 1978) have shown that there quickly comes a point where no further improvement in fit occurs, and the additional new class either looks just like an existing class, or is assigned a probability of zero. This set of classes is referred to as the non parametric maximum likelihood (NPML) estimator of the latent growth distribution. Although the NPML estimator is formed of classes it can be shown that it fully characterizes the latent growth distribution even if that distribution is not one of classes but of continuous variability, as in a traditional growth curve model. In other words, even when the data are continuous, a latent class model with only a small number of classes is often a better fit than a model assuming the continuous variability of the "true" model. As a consequence, showing that a latent trajectory class model fits well is merely to say that we can approximate the latent growth distribution, whatever its true discrete or continuous form, by these classes and not that the classes actually exist. Nonetheless, these models allow for an effective summary of the data, helpful for theory building and constructing tests of clinical interest.

Figure 15.9 shows the classes identified from repeated observational assessments on a group of toddlers, showing the observed scores of the individuals assigned to each class, the mean trajectory of their class and how precisely estimated that trajectory is reflected in a confidence envelope. Such models can be estimated in programs such as the SAS procedure TRAJ, the SEM program Mplus (Muthén & Muthén, 2001) or the general Stata procedure gllamm (Rabe-Hesketh *et al.*, 2000).

One of the major limitations of SEM path models is their inability to represent interactions involving latent variables. In fact, this is not a strict limitation, since multiple group methods (models that allow random coefficients, for example, gllamm, Rabe-Hesketh *et al.*, 2003) and a number of other approaches enable such interactions to be considered (Schumacker & Marcoulides, 1998). Nonetheless, few substantive applications have pursued them.

Causal analysis

SEM is often referred to as causal modelling, but although it can provide a framework within which analysis specifically concerned with attempting to isolate evidence for causation can be undertaken, in practice this is rarely done. There is, however, a quite distinct collection of methods that specifically address causal interpretation. We consider two of these, propensity score weighting and instrumental variables.

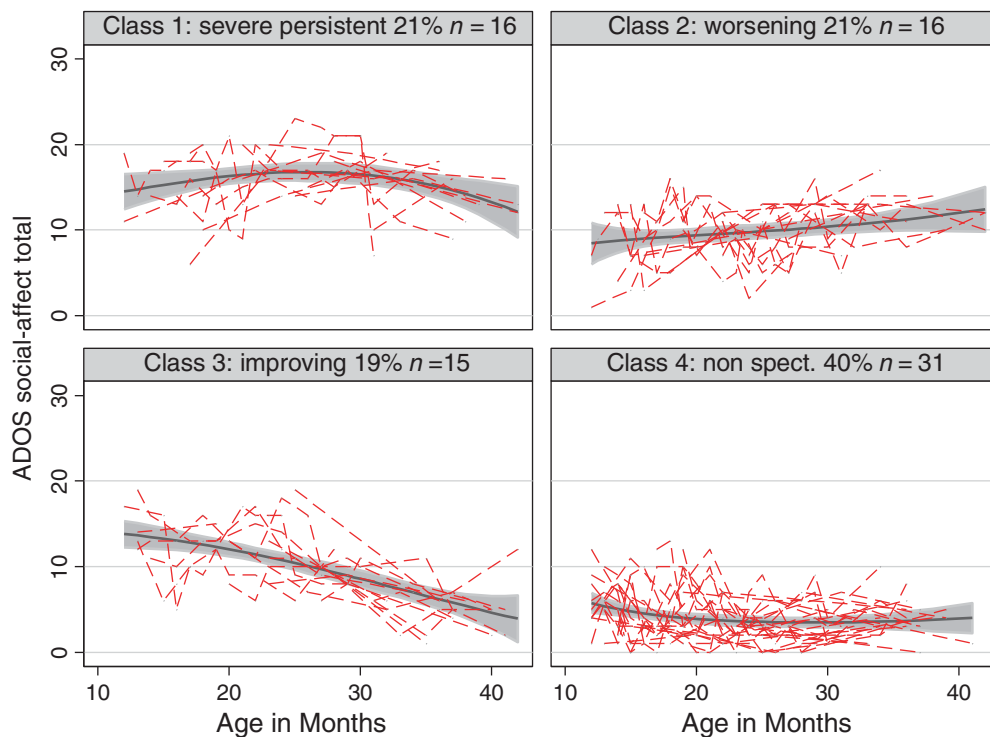

Figure 15.9 Trajectories of early development in ADOS scores (from Lord *et al.*, 2012); (non spect. = non autism spectrum; new algorithm = 2007 scoring of ADOS).

Propensity score approach

Consider the case where, in the population, the effect of X (e.g., smoking) on the outcome Y (e.g., lung cancer) may be confounded only by measured confounders denoted by Z (e.g., socioeconomic status). The propensity score approach allows estimation of the causal effect of X in this circumstance (Rosenbaum & Rubin, 1983). For a binary exposure of interest X , the propensity score for a subject is the conditional probability of exposure given the vector of observed confounders Z . Such a propensity score is usually estimated by logistic regression, with X treated as the response variable and the confounders Z as the predictors. The point estimate of the effect of X from an analysis that also includes the propensity score gives unbiased estimates of the exposure effect under a wider range of conditions than an analysis that covaries for all the variables in Z . For example, if these have greater variability or different patterns of correlation in one exposure group than another, as in Figure 15.3, then direct covariate adjustment would increase the bias or even overcorrect.

An alternative way of using the propensity score idea, proposed by Robins and Rotnitzky (1995), is to weight individuals by the inverse of the probability of experiencing the exposure that they did, that is, $1/\text{propensity score}$ for those that were exposed and $1/(1 - \text{propensity score})$ for those that were not. In this weighted sample, the exposure of interest is no longer correlated with the possible confounders Z and near standard analysis of such a weighted sample, a so-called marginal structural model (MSM), gives estimates of the effect of X unconfounded with effects of Z .

The analysis thus consists of fitting the usual models for the effects of X on Y , for example, linear or logistic regression, but with subjects' weights $\{w_i\}$. Though a subject may be assigned a weight of two, they nonetheless still possess the variability of response typical of a single individual. Standard errors, and thus p values and confidence intervals, are calculated using the sandwich or robust estimator (Huber, 1967; Binder, 1983) or some other technique (such as bootstrap) that recognizes this.

In a longitudinal study we will commonly be concerned with a time dependent exposure, X_0, X_1, \dots, X_k , where we might wish to estimate the effect of a cumulative exposure. With exposures confounded with Z_0, Z_1, \dots, Z_k , we can again use weights for the probability of exposure, but now the weight's denominator is the conditional probability that a subject experienced their particular exposure history.

In the single period case, the practical advantage of the MSM approach over more routine covariate adjustment is not obvious. However in the multi-period time-dependent case, the advantage of the MSM approach is clearer. Both approaches attempt adjustment for Z_k , where Z_k is a confounder for later exposure. However, adopting the simpler covariate adjustment approach erroneously controls for the effect that earlier values of the exposure have on Z_k , that is, the value of the confounder during period k . Thus, it would also wrongly partial out causal effects that should be attributed to the exposure. An example is the study of the effect of antiretroviral therapy (the exposure) and CD4 counts (the confounder) on the risk of acquired immunodeficiency syndrome (Cole *et al.*, 2003). In this study, controlling for CD4 leads to the incorrect conclusion that

antiretroviral therapy does not work. We have yet to see such methods much used in child psychiatry.

Instrumental variables

The propensity score approach described requires full information on all the confounders of the causal effect of the exposure of interest because these are needed to define the propensity score or the inverse probability weights. But almost always there are numerous possible confounders that we simply have not measured. How then do we proceed?

One way to deal with unmeasured confounding involves having data on a variable R that precedes and is related to exposure but is not directly related to the outcome or the unmeasured confounders (Figure 15.10). A variable with these properties, if it exists, is said to be an “instrument” for the unbiased estimate of the causal effect of the exposure. If all relations are linear, then the instrumental variable estimate of the causal effect is the ratio of the coefficient in the regression of Y on R , and the coefficient in the regression of X on R . With adjustment for measured confounders and multiple instruments the estimation is more complex, though programs are commonly available.

The main problem with this method is that it is rare to identify good instruments. Most examples exploit the occurrence of “natural experiments” (see Chapter 12). Examples include using the Vietnam draft lottery number to examine the effects of traumatic event exposure (Hearst *et al.*, 1986) and geographical variation in treatment provision to assess treatment impact on autism (Lord *et al.*, 2006). More recent novel applications include an example of Mendelian randomization. In this approach, (presumed) functional genes are used as instruments for phenotypes thought to cause certain diseases (Davey-Smith & Ebrahim, 2005).

Of course the most obvious source of an instrument is from deliberate randomization within an actual experiment. In this context, the approach is becoming increasingly popular. The standard intention-to-treat estimator estimates the average effect of the treatment for everyone who was assigned for treatment, ignoring whether anyone actually took any of the treatment to which they were assigned or not. This declines in interest as the proportion of non compliers with treatment increases, and we may want to know what the treatment effect would be on those who would take it if offered. Provided that the effect of being randomized to treatment was to increase exposure to the treatment of interest (and that certain other

assumptions are met; cf. Dunn *et al.*, 2005), then an unbiased effect for this subgroup is estimable using instrumental variable methods; whereas the naïve estimates, such as the so-called the per-protocol effect estimate is biased.

Mediation

A mediation analysis attempts to decompose a causal effect into components that occur along particular causal pathways. It thus falls squarely within the literature of the previous sections, as a topic that has received special attention. Recent work in statistics has attempted to place the more informal early work (Judd & Kenny, 1981; Baron & Kenny, 1986) onto the more formal footing of counter-factual theory, and has attempted to address two problems of mediation research. The problem is that though, in an RCT, the effect of treatment on mediator can be validly estimated, our estimates of the effect of mediator on outcome remain potentially biased due to both confounders and measurement error in the mediator (Dunn & Bentall, 2007; Dunn *et al.*, 2013).

Missing data

Missing data are a common problem and can arise for a variety of reasons ranging from missing questionnaire items to attrition from the study. There are three categories of missing data (Little & Rubin, 1987, 1989): missing completely at random (MCAR), missing at random (MAR) and non ignorable missing. When missing data are completely random, the “missingness” does not depend on the values of either observed or latent variables, and analysis of complete data cases only does not lead to bias. This is the strategy adopted by the majority of research in psychology using list-wise deletion. However, in reality, missing data are rarely unrelated to observed and latent variables, and so this approach is typically biased. MAR assumes that missingness is related to observed, but not latent variables or missing values. For example, if sex influences missingness on a language test, but within males and females separately language ability itself does not relate to the missingness of language test data, then for a model including sex the missing data are MAR, whereas for a model that ignores sex they are not. Though the assumptions of MAR are weaker than MCAR and are more likely to hold in reality, it is not actually possible to test for MAR because the missing data scores are unknown. When missingness is dependent on both observed and unobserved values, missing data are non ignorable, for example, where those with higher depression have more missing data because they were less likely to come in for the study. Such missingness requires more specialist and speculative methods and is probably better thought of as part of a sensitivity analysis testing the robustness of findings (White *et al.*, 2011).

An increasingly popular approach for tackling missing data is multiple imputation (MI; Schafer, 1999). Several datasets that have the same observed data have missing data filled in with values that differ between datasets, the variability depending upon the uncertainty of the missing values. Each dataset is

Figure 15.10 Confounding of the causal relationship of X to Y by U and the instrumental variable R .

analyzed and the results pooled using simple formulae (Rubin, 1987) which uses the variability in results from dataset to dataset as the source of the information on how the missing data contributes to uncertainty. In trials, MI for missing baseline data is now common and while the trial outcome data should be included in the imputation step, the general recommendation is that the imputed outcome data be dropped and instead this be accounted for through the usual MAR assumptions of standard maximum likelihood analysis. This is an example of the now common practice of using several different approaches for dealing with different aspects of missing data.

Although MI methods are increasingly common and easy to undertake, mistakes are easy to make, for example, examining sex differences when the imputation model assumed relationships between variables were the same for males and females. Since the MI step is rarely fully described, such mistakes are hard to detect.

Screening, diagnosis and misclassification

As with continuous measures, measurement errors in the form of misclassification of categorical variables can have pernicious effects that lead to widespread misunderstanding. For example, when measuring a category, say present or absent, observers may agree with each other even when simply guessing. Where raters score a category as present just 1% of the time, then the percentage agreement is expected to be 98% even when they score blind to all information. Thus we prefer to use the so-called “chance-corrected” measures of agreement (Dunn, 2000) such as kappa statistics that give credit only for agreement in excess of that obtainable by blind guessing. Where we know the true status then we can also calculate the proportion of true positives that are correctly rated (sensitivity), the proportion of true negatives that are correctly rated (specificity), the positive predictive value (PPV) and the negative predictive power (NPV) and likelihood ratio (LR). Which of the various measures one wants to optimize depends on the purpose of the measure and its context of use.

As part of the impact of “big data” there have been a plethora of claims of high diagnostic validity for an array of biological measures. The multiple testing problem is severe; analysts will inevitably find some features among the hundreds of thousands available, that will by chance discriminate among, say, the 50 children with ADHD and the 50 with depression. While we have developed clever methods to remove bias in estimated classification success, such as leave-one-out cross-validation, these are commonly applied only to the last stages of the study. It is not unusual to start with 50 brain or genetic features suggested by the literature as possible discriminators and then analyse with sound cross-validation methods the available samples, but fail to point out that these same samples had also been used in the preliminary selection of the 50 features. It is also commonplace to report in the context of groups that are 50 : 50 case and non case

but then fail to highlight that a seemingly small false-positive rate can make a test useless if the disorder is rare within the population in which the test is to be applied.

Reporting results

Although statistical modelling may be increasingly used as the principal analysis tool, authors should nonetheless be expected to present tables and figures that display the essential features of the raw data. For the reporting of results from trials, guidelines exist (e.g., www.consort-statement.org), while for epidemiologic studies such guidelines are developing (e.g., www.strobe-statement.org). Estimates of effects should be reported in both standard form and in other ways that help interpretation. For example, treatment effects are often reported in terms of both reductions in risk and the number needed to treat in order to cure or avoid one case/death (equal to one over the absolute risk reduction).

In observational studies, where causal interpretation is felt justified, quantities like population attributable fraction (the fraction of cases that could be avoided if the risk exposure could be eliminated) can be helpful. More generally, comparing and describing results based on continuous variables and discrete/group-based analysis is to be encouraged, since these two approaches offer quite different insights and strengths and weaknesses (Pickles & Angold, 2003). As far as possible, results should present both the evidence for and against the principal conclusions. In this respect, we have mentioned how estimates and confidence intervals are preferred to significance levels alone.

A growing problem for the quality of reporting of results is the demand for “hype,” whether from the increasing ubiquitous institutional press office, the demand of funders for “impact” or even the competition among editors for a higher journal impact factor. These are corrupting influences, requiring us to be astute and alert for misrepresentation of one’s own reports and those of others.

Conclusions

This chapter has highlighted just some of the careful considerations required in undertaking, interpreting and reporting data analysis. The chapter does not provide an exhaustive overview of statistical methods and there are many useful and important tools that we have omitted. The principal message is that statistical science is not a set of recipes, nor a set of hurdles that must be jumped to get to publication, but a set of concepts and principles whose application delivers better science and helps protect us from the fraudulent claims of those with vested interests or merely the well meaning but misguided. Our introduction also contrasted differences between experimental and observational studies, highlighting the different cultures. Those who

have undertaken an RCT, especially one with an experienced specialist clinical trials unit, will attest to the unrelenting pre-specification required for all aspects and contingencies of the study. Increasingly, those doing observational studies are rightly being urged to adopt as much as possible of this pre-specified attention to detail so as to avoid often unintended but cumulative biases that have undermined the field. Similarly, more is being demanded of experimentalists, pressing them to answer questions for which randomization alone is not the cure-all (e.g., mediation analysis). As both trends occur, the two cultures are being brought together, hopefully each achieving a more mature understanding as well as greater convergence in findings.

CHAPTER 16

Global psychiatry

Atif Rahman¹ and Christian Kieling²

¹Institute of Psychology, Health and Society, University of Liverpool, UK

²Department of Psychiatry, School of Medicine, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil

Introduction

Health and disease are universals. The field of child and adolescent psychiatry has undergone significant developments over the last decades, but this progress has not been uniform in all areas of the globe. The growing interconnectedness among nations, and the fact that nine out of ten individuals under the age of 18 years live in low and middle income countries (LMIC), has led to an increased attention to the global aspects of child and adolescent mental health in recent years.

The contemporary concept of global health—the study and practice of improving health and health equity worldwide through international and interdisciplinary collaboration—derives from the fields of public health and international health, which in turn have their origins in tropical medicine (Koplan *et al.*, 2009). Global health can also be understood as health issues that transcend national borders and which may be better addressed from cooperative action (Institute of Medicine, 1997). Other definitions propose that the field: (1) refers to any health issue that affects many countries and is affected by transnational determinants, (2) is more concerned with the scope than with the geography of problems, (3) encompasses the complex interactions between societies, (4) uses the resources, knowledge and experiences of different societies to deal with health challenges around the globe, and (5) includes basic sciences, prevention, treatment and rehabilitation (Koplan *et al.*, 2009).

In a way, contemporary conceptualizations of global health are not very distinct from the initial goals established for the World Health Organization (WHO): “the attainment by all peoples of the highest possible level of health.” Over the years, however, the global scenario has changed from the reality of 1948, when the WHO was created; there is now a growing interdependence among states, societies and economies, which brings both increases to the number of threats common to several countries and new opportunities for collaboration between

nations (Skotheim *et al.*, 2011). The concept of international health, for example, was already used in the late 19th and early 20th centuries, when referring especially to a focus on epidemic control at the borders between nations. The term global health, in turn, implies consideration for the health of all people on the planet, above concerns specific to countries and national boundaries. Both concepts, of course, are not mutually exclusive, sharing many points of overlap (Brown *et al.*, 2006).

Historical context of global health

The boom in international travel, the economic globalization, and the occurrence of pandemics such as the 2009 Influenza A outbreak have magnified awareness of global health issues. Historically, the Age of Exploration, which started early in the 15th century and continued through the 17th century, is regarded as a turning point in global health. In sailing West to reach the Indies by crossing the Atlantic, the Europeans landed on the “new world” and brought on not only the advancement of cultural exchange, but the unification of the microbial world: their arrival in the Americas was accompanied, for example, by the appearance of measles, smallpox, and yellow fever on the continent. It was only in the 19th century, however, that advances in knowledge about the causes of these diseases and the development of effective therapies, along with the recognition of the fundamental rights of all human beings, led to concrete efforts to fight such problems in the international arena (Berlinguer, 1999).

Until recently, the field of global health remained focused on communicable diseases, such as measles, polio, diarrheal diseases, and most significantly HIV infections. The focus on neglected tropical diseases (such as tuberculosis and malaria) strongly dominated the field of global health in the second half of the 20th century. With the increase in life expectancy—especially in the last century, when there was more than half of the gain in number of years lived in the last

five millennia—developing nations underwent a demographic transition that led to the so-called “double burden” of disease: the persistence of communicable diseases was accompanied by an increase in chronic conditions.

Mental health in the context of global health

The growing impact of chronic noncommunicable diseases (CNCD) has put this group of diseases in the current focus of attention in the global health discussion (Nugent & Jamison, 2011). CNCD, which include cardiovascular disease, cancer, and diabetes mellitus, are the largest cause of death in the world, being responsible for 63% of deaths worldwide, 80% of them in LMIC. Recognition that schizophrenia, depression, epilepsy, dementia, alcohol dependence, and other mental, neurological, and substance-use (MNS) disorders constitute a large proportion of the global burden of disease has drawn attention to the particular impact of mental health problems on the emerging field of global health.

Global mental health has been defined as the application of the principles of global health to the field of mental health (Patel & Prince, 2010). The neglect of mental health problems at different levels of health care in various countries, both rich and poor, led Arthur Kleinman to describe efforts in global mental health as a “failure of humanity” (Kleinman, 2009). Statistics are now available that show how the impact of mental disorders contrasts with the limited access to care and evidence-based treatments, particularly in resource-poor settings.

It is estimated that 30 million people will try and 1.5 million die from suicide annually by 2020. Even not being among the main direct causes of mortality, MNS already accounted for 12.3% of the global disease burden in 2000, and that proportion is expected to increase to 16.4% in 2030 (Collins *et al.*, 2011). These figures possibly reflect an underestimation of the real impact of mental health problems. Mental disorders increase the risk for communicable and noncommunicable diseases and contribute to intentional and accidental injury (O'Connor *et al.*, 2000). Conversely, many diseases increase the risk for the occurrence and perpetuation of mental disorders, and the presence of comorbidities is also a factor that hinders the search for help, diagnosis and treatment of different diseases (Ickovics *et al.*, 2001). There is no doubt, therefore, that there is no health without mental health (Prince *et al.*, 2007).

Child mental health in the context of global mental health

Initially focused on the so-called common and severe mental disorders, the study of global mental health more recently has also adopted a developmental perspective, prioritizing the care of children and adolescents. The study of mental health of children and adolescents is a relatively new field. The substantial growth that this area has shown, however, has not occurred uniformly across the globe. There has been significant progress in the description of syndromes and disorders, today nosologically better defined; in the early identification of individuals at risk

for developing mental disorders; in the elaboration of preventive and therapeutic evidence-based interventions; and in the implementation of health services that provide such knowledge in various social and cultural contexts. Such advances, however, are not available to the vast majority of the 2.2 billion children and adolescents in the world, particularly in LMIC.

Individuals under the age of 18 years represent almost a third of the entire world's population—and 90% of them live in LMIC, where they constitute up to half of the population in some cases. To a large extent, the enormous burden imposed by mental disorders is attributable to their early incidence in life and to their persistence into adulthood and old age. Prospective data collected from childhood and retrospective studies in adulthood converge to demonstrate that a significant proportion of psychiatric diagnoses among adults have their roots early in life. Additionally, among the major causes of health-related burden for youth aged 10–24 years, three are specific psychiatric diagnoses and the other two are linked to mental health problems: unipolar depressive disorders accounts for 8.2% of all disability-adjusted life years (DALYs) in this age group; road traffic accidents, 5.4%; schizophrenia, 4.1%; bipolar disorder, 3.8%; violence, 3.5% (Gore *et al.*, 2011). Figure 16.1 presents the burden of mental and behavioral disorders according to the 2010 Global Burden of Disease Study (Murray *et al.*, 2012).

The economic case for early investments in global child mental health

It is evident that global child and adolescent mental health is at the center of global mental health—and, subsequently, essential to achieve global health in general. Advances from developmental science indicate that the first years of life represent a window of opportunity to prevent the onset and chronicity of mental health problems. Interventions early in life represent opportunities for long-term health and socioeconomic benefits by reducing the incidence of mental health problems and decreasing their persistence as chronic disorders. This is in accordance with the economic arguments for early investments in the promotion of human capital. The model developed by Heckman and Krueger (2003) proposes that assuming the same investment is made at different points in time over the lifecycle, interventions made in the womb have a higher rate of return than those conducted at later ages: the returns to earlier investments can be reaped over longer time periods, and as capabilities (cognition, physical, and mental health) exhibit both self- and cross-productivity, an early investment has multiple positive effects (Angelucci & DiMaro, 2010). In the absence of longitudinal studies, it is difficult to substantiate the model with hard evidence. One systematic review of 42 effectiveness trials and program assessments of early preventive interventions (e.g., parenting support and education, preprimary or preschool centers, educational media for children), demonstrated that early child development can be improved through these interventions with effects greater for programs of higher quality and for the most vulnerable children, and

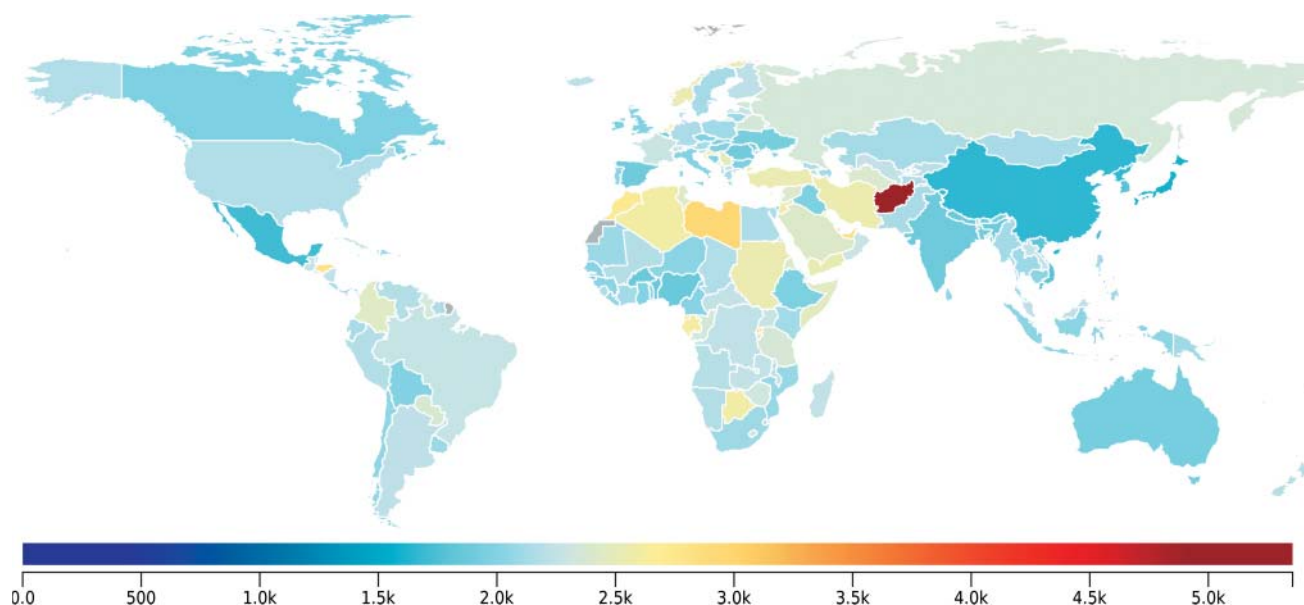

Figure 16.1 The burden of mental and behavioral disorders affecting individuals aged 10–14 years in 2010 (in DALYs/100,000 individuals). *Source:* Extracted from <http://viz.healthmetricsandevaluation.org/gbd-compare>. Institute for Health Metrics and Evaluation (IHME). GBD Compare Seattle, WA: IHME, University of Washington, 2013. Available from <http://vizhub.healthdata.org/gbd-compare/#>. Accessed November 26, 2014.

that effective investments in early child development have the potential to reduce inequalities perpetuated by poverty, poor nutrition, and restricted learning opportunities (Engle, 2011). To demonstrate the economic effect of early child development interventions, the authors developed a simulation for one program that focussed on preschool enrollment of children to enhance early cognitive development. This showed a benefit of \$10.6 billion for increasing preschool enrollment to 25% in all countries, and \$33.7 billion for increasing to 50%, with a benefit-to-cost ratio as large as 17.6–1.

Context heterogeneity

The variety of contexts in which the 2.2 billion children and adolescents in the world live has an impact on their mental health (Kieling *et al.*, 2011). Unfortunately, limited research has been dedicated to systematically study the characteristics of the environment across different countries. For instance, there is a gap in the literature in terms of how cultural heterogeneity affects attitudes towards children. In the absence of operational criteria to classify countries according to multiple environmental factors, the use of economic standards has prevailed in most of the international comparative research.

The most frequently used criterion is the World Bank's classification of economies, a measure that is based on their gross national income (GNI) per capita. The reasons for choosing this index to classify countries include a relative stable correlation with measures of general well-being, such as poverty and infant mortality, and arguments that it would constitute the “best single indicator of economic capacity and progress” (World

Bank, 2013a, b). According to their GNI per capita, economies are classified as low income, middle income (subdivided into lower middle and upper middle), or high income. The GNI of all economies are converted to US dollars using the so-called Atlas conversion factor (to reduce the impact of exchange rate fluctuations in the cross-country comparison). In 2011, the values for each group were the following: low income, \$1025 or less; lower middle income, \$1026–\$4035; upper middle income, \$4036–\$12,475; and high income, \$12,476 or more (World Bank, 2013a, b).

However, owing to the heterogeneity within populations, the GNI per capita method loses precision in nations with larger population sizes, such as China or India, with populations over 1 billion individuals. Moreover, from a global perspective, immediately after these two countries crossed the threshold to the middle-income category a few years ago, the majority of individuals in the world living in poverty (less than \$1.25 per day) were classed as living in middle-income countries. An alternative criterion to classify countries according to their development level is the human development index (HDI), a measure based on three indicators: life expectancy at birth; educational level (measured as a combination of the literacy rate and primary, secondary, and tertiary education level enrollment rates); and per capita gross national product (UNDP, 2013). This illustrates the complexity of synthesizing evidence from within LMIC and extrapolating evidence from high income countries (HIC) to LMIC.

Although evidence from both HIC and LMIC converges to associate poverty with emotional, behavioral and developmental problems, other environmental factors have also been identified to negatively affect the mental health of children and

adolescents. Knowledge about such factors can be valuable when policy and services are being planned in low resource areas.

Poverty

Research funded by UNICEF (Gordon *et al.*, 2003) to investigate childhood poverty in 46 countries in the developing world showed that over 1 billion children suffer from severe deprivation of basic human needs and over a third lived in absolute poverty. The association between childhood poverty and adverse physical, cognitive, educational, social, and emotional outcomes has been extensively studied, mostly in HIC (Yeung *et al.*, 2002; Engle & Black, 2010). Poverty influences children's developmental outcomes through various pathways. Poor children are more likely to grow up in less stimulating environments, to experience increased psychological distress related to monetary difficulties and to suffer from harsh parenting practices. These negative effects have been found in LMIC, where prevalence rates of poverty are much higher. Fleitlich & Goodman (2001) carried out a cross sectional survey of school children between the ages of 7–14 years in three contrasting neighborhoods in a Brazilian district, a shanty town, a stable urban neighborhood and a rural village and found significant associations of child mental health problems with poverty as well as with maternal mental illness and witnessing family violence.

The project Young Lives is an international collaborative research project about child poverty, involving a large cohort of children from four developing countries, Peru, Vietnam, Ethiopia, and India (Dercon & Krishnan, 2009). Within a cohort of over 4000 12-year-olds, they found that measures of self-efficacy, sense of inclusion, self-esteem, and educational aspirations all correlate with measures of material well-being of the family in which the children were growing up, suggesting a link between economic circumstances and broader dimensions of childhood well-being.

Economic disparity and social inequality between groups living in the same country can be risk factors in their own right (Walker *et al.*, 2011), especially in the context of early child development. The impact of relative poverty and associated psychosocial adversity on child mental health is discussed in Chapter 26.

Malnutrition

Recent success in reducing childhood mortality rates in developing countries has left hundreds of millions of children living in poor conditions with neurodevelopmental delays that receive minimal attention (Susser, 2012). In LMIC, almost a third of all children under the age of 5 are reported to suffer from clinically relevant undernutrition, defined as height-for-age below -2 SD of reference values (UNICEF, 2006). Malnutrition has a clear impact on children's development, including motor, language, and cognitive abilities (Grantham-McGregor, 2007). Controlling for socioeconomic covariates, prospective cohort studies consistently show significant associations between stunting by age 2

or 3 years and later cognitive deficits, school achievement, and dropout (Walker *et al.*, 2007).

Intellectual disability

LMIC have higher rates of intellectual disability (Institute of Medicine, 2001). A recent meta-analysis of 52 population studies published between 1980 and 2009 found a prevalence of intellectual disability of 10.3/1000, with the highest rates in low income countries, where the prevalence/1000 population was 16.41 (Maulik *et al.*, 2011).

Children with intellectual disability also have markedly increased prevalence of psychiatric disorders. A systematic review found prevalence rates between 30% and 50% (Einfeld *et al.*, 2011). In children with intellectual disability, the most commonly associated comorbid psychiatric disorders are autism spectrum disorder, ADHD, and conduct disorder (Matson & Shoemaker, 2009). Emerson and Hatton (2007) found that a significant proportion of the increased risk of psychiatric disorder could be accounted for by the increased risk of psychosocial disadvantage experienced by children with intellectual disability, which has important policy and public health implications for developed and developing countries alike. Furthermore, without intervention, psychopathology tends to persist into adulthood (Einfeld & Emerson, 2008).

Orphans and vulnerable children

Over 140 million children in developing countries—or one in every 13—are orphans (Cluver & Gardner, 2007). In particular, the AIDS epidemic has been a driving force of vulnerability for children, leaving more than 25 million orphans and vulnerable children worldwide (Santa-Ana-Tellez *et al.*, 2011). A review of studies on the mental health of children orphaned by AIDS found that out of 13 studies measuring internalizing problems, 10 reported evidence of increased difficulties, whereas three out of seven found evidence of externalizing behavior difficulties (Cluver & Gardner, 2007).

War and terrorism

War and terrorism expose children to a range of risk factors. Emotional and behavioral consequences include acute stress reactions, post-traumatic stress disorder, anxiety and depressive disorders, regressive behaviors, and sleep and behavior problems (Fremont, 2004). Studies have found that the majority of youth exposed to war/violence experience severe and enduring threats that place them at increased risk for derailment in their developmental trajectory and that the chronicity of the trauma precludes them from recovery (Kletter *et al.*, 2013). War and terrorism also expose children and adolescents to a range of negative situations, such as the risk of dislocation, separation from family and loss of loved ones (Joshi & O'Donnell, 2003) (see Chapter 44). The number of conflict-related traumatic experiences has been shown to correlate positively with the prevalence of mental, behavioral, and emotional problems in

children and adolescents living in conflict zones in the Middle East. Prevalence of post-traumatic stress disorder in children and adolescents is estimated to be 5–8% in Israel, 23–70% in Palestine and 10–30% in Iraq (Dimitry, 2012).

In summary, poor children growing up in LMIC encounter several contextual risk factors for mental disorders. Prevention, diagnostic and intervention programs and services focused on LMIC should not simply mirror those in developed countries but need to recognize the specific risk profiles facing these children. Although usually more frequent in LMIC, some contextual risk factors for mental disorders also affect children and adolescents growing up in HIC. In fact, data from HIC suggests that a substantial proportion of young individuals in these countries are also exposed to negative environments. The recent UNICEF Report Card 11 presented data on the well-being of children living in 29 rich countries, focusing on five dimensions of children's lives: material well-being, health and safety, education, behaviors and risks, and housing and environment. The Netherlands was the only country ranked among the top five in all dimensions, also exhibiting the best self-rated scores (when children evaluated their own well-being). The Nordic countries Finland, Iceland, Norway and Sweden occupied the next places in the well-being rank. Although among the four bottom places three were of the poorest countries in the survey (Latvia, Lithuania, and Romania), it was noticeable that the other nation in this group was the United States, suggesting that there was no overall strong relationship between per capita GDP and overall child well-being (Bradshaw *et al.*, 2013; Martorano *et al.*, 2013). A possible explanation for the low well-being estimates in the United States can also be the combination of general economic affluence with high poverty rates among children.

Methods in global child and adolescent psychiatric epidemiology

Population-based surveys from both HIC and LMIC demonstrate the high prevalence of mental disorders affecting children and adolescents in various nations. Despite the wide range of prevalence estimates (discrepancies occur both in HIC and LMIC studies), a large proportion of the surveys estimate that between 10% and 20% of children and adolescents have at least one diagnosable mental disorder according to major diagnostic classifications (the Diagnostic and Statistical Manual of Mental Disorders (DSM) or the International Classification of Diseases (ICD) (Kieling *et al.*, 2011)—Table 16.1.

In addition to the variability in terms of instruments used and data collection strategies, much of the epidemiological research on childhood and adolescence mental disorders has limited methodological rigor. The use of similar instruments, survey strategy and design need to be analogous in order to allow for comparison of data such as prevalence rates. Without such data, limited conclusions can be derived from patterns of occurrence

of both mental disorders and risk factors (such as those covered in the previous section). This reiterates not only the need for conduction of surveys along the lines of the World Mental Health Survey Consortium (Demyttenaere *et al.*, 2004), but with focus on the pediatric population, but also some degree of standardization in terms of measurement of risk and protective factors.

Adaptation of instruments is a process that requires a team composed of multiple experts in order to find balance between literal translation and culturally specific translation, making use of back-translations as a feedback method for the translation of content and intent. Further field-testing in small pilot groups with subsequent larger datasets collection is also essential to qualitatively and quantitatively identify flawed items, establishing reliability, validity, and new norms (Widenfelt *et al.*, 2005). Specifically, cross-cultural studies have frequently assessed the reliability rather than the validity of constructs across different cultural groups (Hollifield *et al.*, 2002; Saxena *et al.*, 2006a, b; Betancourt *et al.*, 2009). In this sense, disentangling methodological and cultural effects that contribute to variability in prevalence estimates has been a continuous challenge in pediatric psychiatric epidemiology (Canino & Alegría, 2008).

Culture can affect the presentation of psychopathology in multiple ways; for instance, by creating and reinforcing specific sources of distress and impairment or by influencing the interpretation of symptoms (Rohde, 2011). Cultural aspects are also relevant to the perception of what represents a mental health problem and how preventive or therapeutic interventions can be implemented in distinct areas of the globe—for example, a desired behavior in one culture can be unacceptable in another.

Diagnostic interviews and questionnaires with more than five studies (each with at least 300 children) from different societies have been assessed in a recent review that described the performance of both categorical and dimensional instruments. This study confirmed the marked disparities in estimates even when using the same diagnostic instrument in different populations: for categorical diagnoses, at least one disorder was present in 1.8% of children and adolescents in India and in 12.7% of young individuals in Brazil when using the Development and Well-Being Assessment (DAWBA) and ranged from 8.8% in New Zealand to 50.6% in areas of the United States and Puerto Rico for the Diagnostic Interview Schedule for Children (DISC) (Achenbach *et al.*, 2012).

Dimensional instruments have also demonstrated to be valuable in the assessment of psychopathology in different contexts, such as the Strengths and Difficulties Questionnaire (SDQ; translated into more than 75 languages and freely available at www.sdqinfo.com), and the Achenbach System of Empirically Based Assessment (the ASEBA set of instruments, including the Child Behavior Checklist [CBCL], and the Teacher Report Form [TRF]; translated into more than 80 languages and commercially available at www.aseba.org). The ASEBA set of

Table 16.1 Studies on the global prevalence of child and adolescent mental disorders in LMIC.

Study	Country	Income (WB)	Sample frame	Diagnostic systems and instruments	Information sources and strategy for combining information	Number of stages	N	Attrition study completion rate %	Age range/mean (SD) (years)	Prevalence rates in % (CI/SE)
Mullick & Goodman, 2005	Bangladesh	Low	Regional community, urban and rural	ICD-10; SDQ & DAWBA	Parents, children (<11 yr) and teachers; best estimate	2	922	75	5–10	15 (11–21)
Anselmi <i>et al.</i> , 2010	Brazil	Upper middle	Regional community, urban and rural	DSM-IV/ICD-10; SDQ & DAWBA	Parents and adolescents; best estimate	2	4445	84.7	11 & 12	10.8 (7.1–14.5)
Bilyk & Goodman, 2004	Brazil	Upper middle	Regional school, urban and rural	DSM-IV; DAWBA	Parents, children (<11 yr) and teachers; best estimate	1	519	83	7–14	12.7 (9.8–15.5)
Goodman <i>et al.</i> , 2005	Brazil	Upper middle	Regional community, rural	DSM-IV; SDQ & DAWBA	Parents, children (<11 yr) and teachers; best estimate	2	1251	94	5–14	7 (2.3–11.8)
Guan <i>et al.</i> , 2010	China	Lower middle	Regional, school, urban and rural	DSM-IV; ISICMD & structured interview designed by authors	Parents	2	9495	NA	5–17	16.22 (15.49–16.97)
Fekadu <i>et al.</i> , 2006	Ethiopia	Low	Regional, school, urban	DSM-III-R; DICA	Children	1	528	NA	5–15	12.5 for school children; 20.1 for laborer children; ^c 16.5 combined
Hackett <i>et al.</i> , 1999	India	Lower middle	Regional community, rural	ICD-10; Rutter scales A/B & clinical assessment	Parents	2	1403	95	8–12	9.4 (7.9–10.8)
Malhotra <i>et al.</i> , 2002	India	Lower middle	Regional school, urban and rural	ICD-10; CPMS/Rutter B scale & clinical interview	Parents, and teachers; best estimate	3	963	91.7	4–11	6.33
Pillai <i>et al.</i> , 2008	India	Lower middle	Regional Community, urban and rural	DSM-IV; DAWBA	Adolescent (half sample) and adolescent and parents (half sample)	1	2048	76	12–16	1.81 (1.27–2.48)

Srinath <i>et al.</i> , 2005	India	Lower middle	Regional community, urban and rural	ICD-10; SCL and VSMS/ CBCL & DISC (4–16 yr) and clinical assessment (0–3 yr)	Parents and children; best estimate	2	2064	90.5	0–16	13.8 (10.6–17) for 0–3 yr; 12 (10.3–13.6) for 4–16 yr; combined = 12.5
Kasmini <i>et al.</i> , 1993 ^b	Malaysia	Upper-middle	Regional community, rural	ICD-9; RQC & FIC	Parents; best estimate	2	507	99.6	1–15	6.1
Benjet <i>et al.</i> , 2009	Mexico	Upper middle	Regional community, urban	DSM-IV; WMH-CIDI	Adolescent	1	3005	71	12–17	39.4 (38–40.9)
Abiodun, 1993 ^a	Nigeria	Lower middle	Regional community, rural	ICD-9; RQC & FIC	Parents	2	200	NA	5–15	15
Goodman <i>et al.</i> , 2005	Russia	Upper middle	Regional school, urban and rural	ICD-10; SDQ & DAWBA	Parents, children (<11 yr) and teachers; best estimate	2	448	74	7–14	15.3 (10.4–20.1)
Wacharasindhu and Panyayong, 2002	Thailand	Lower middle	Regional, school, urban	DSM-IV	Parent, teacher, child ^d	2	1480	83	8–11	37.58
Alyahri & Goodman, 2008	Yemen	Lower middle	Regional, school, urban and rural	DSM-IV; SDQ & DAWBA	Parents and teachers; best estimate	2	1210	91	7–10	15.7 (11.7–20.2)

^aAlthough reported as a two stage study, the second stage was not adjusted for the performance of the screening test in the first stage. So, technically it is a one-stage study (second stage = random subsample of the first stage).

^bOnly screening positives assessed in the second stage.

^cThis was a convenience sample.

^dNot clear how the information from different sources was combined.

RQC = Reporting questionnaire for children; FIC = Follow-up interview for children; NA = not assessed or not available; CPMS = Childhood Psychopathology Measurement Scale (Indian adaptation of the CBCL); SCL = Structured Interview Schedule; VSMS = Vineland social maturity scale; ISICMD = Investigation Screening Inventory for Child Mental Disorders; GHQ-12 = General Health Questionnaire—12 questions version; CDI = child depression inventory.

When the study reported on prevalence rates from different waves of assessment, we opted for including the prevalence rate of the first wave. When in addition to point prevalence/period prevalence (e.g., 12 month prevalence), lifetime prevalence was also presented, we included point prevalence/period prevalence to make findings comparable as the majority of studies report on this type of prevalence.

Source: Extracted from Kieling *et al.* (2011).

instruments was assessed in another recent study, in which data for 44 societies were presented, probably the most successful effort to compare studies across different cultures (Rescorla *et al.*, 2012). Age and gender patterns remained relatively stable across the international level, and a confirmatory factor analysis supported the proposed syndromes when tested separately in each context. However, although many societies showed comparable average scores, nine studies presented scores one standard deviation above and another seven studies one standard deviation below the overall mean. The authors proposed a categorization of societies according to low, medium, and high norms, thus allowing for specific set of norms to reflect regional variations. Despite the huge efforts that such studies represent, it is important to note that even for the most frequently used instrument (the CBCL) no data are currently available for more than 1.4 billion children and adolescents—those living outside the 44 societies investigated. Another factor to be taken into account is the fact that samples were mostly regional and not representative of entire countries, but heterogeneity within countries can be even greater than between nations (Kieling & Rohde, 2012a, b).

Challenges and opportunities

Despite the widespread recognition of the importance of mental health promotion and prevention in children and adolescents, there is an enormous gap between needs and resource availability (Belfer 2008). Building technical and scientific capacity in low resource settings has been recognized as a crucial step toward decreasing the global burden of disease. In many LMIC there is less than one psychiatrist per 100,000 people, and in most countries investment in mental health represents less than 1% of investments in health as a whole (Saxena *et al.*, 2006a, b). Despite the availability of cost-effective treatments for childhood and adolescence mental health problems, there is a huge gap between needs and implementation worldwide.

In order to reduce the gap, the World Health Organization (WHO) launched the Mental Health Gap Action Programme (mhGAP) to scale up services for people with mental disorders, especially in LMIC (WHO, 2008). One essential component of mhGAP is to develop management recommendations (guidelines) for mental disorders identified as conditions of high priority (Dua *et al.*, 2011). The priority conditions in children and adolescents include depression, psychosis, bipolar disorders, and developmental and behavioral disorders. The priority conditions were selected because they represent a large burden in terms of mortality, morbidity, or disability, have high economic costs, and are often associated with violations of human rights. WHO established a Guideline Development Group in 2008 to develop evidence-based recommendations that adhered to the Grading of Recommendations Assessment, Development and Evaluation (GRADE) principles for developing transparent, evidence-based WHO guidelines (Barbui *et al.*, 2010). The

guidelines recognize that in most LMIC settings, the interventions would be conducted by nonspecialist primary care personnel—feasibility was therefore a key consideration. The guidelines are summarized in Table 16.2. Further research, especially of the implementation type, is required to translate these guidelines into scaled-up services.

Research

It can be argued that evidence-based information is probably even more critical to the less developed settings, where resources are scarce. Research plays a crucial role in defining the local needs, assessing the required cultural adaptation strategies, evaluating already implemented actions, identifying potential barriers and monitoring results (Thornicroft *et al.*, 2012). In fact, general health professionals believe that research conducted in their own country is more likely to change clinical practice (Guindon *et al.*, 2010). Therefore, dissemination of scientific research plays a pivotal role in the development and implementation of evidence-based health policies and practices such as those proposed by the WHO mhGAP guidelines. Notwithstanding almost 90% of all children and adolescents in the world live in LMIC, only 10% of randomized controlled trials assessing treatments for mental health problems for this population come from LMIC (Figure 16.2). Of note, the vast majority of intervention research conducted in LMIC assessed psychopharmacological strategies, neglecting the need for culture-specific psychosocial interventions. Thus, WHO guidelines rely on evidence generated from HIC to produce their guidelines, and further research is required to culturally adapt these recommended interventions to their settings. Indeed, evidence from a recent meta-analysis suggested that psychosocial treatments for depression that underwent cultural adaptation exhibit larger effect sizes in terms of effectiveness (Chowdhary *et al.*, 2013).

A recent survey in the Web of Science database for items published in the 2002–2011 decade showed that, although the field of child and adolescent mental health grew from nearly 5000 items published in 2002 to more than 10,000 in 2011, marked discrepancies exist according to income classification of countries. While the immense majority of indexed items (90.69%) had at least one author from a HIC, authorship from LMIC was modest, concentrating predominantly among upper middle income countries (7.79%). Authors from lower middle and low income countries were present in 1.19% and 0.33% of the items, respectively. Confirming these results, GNI per capita was linearly correlated ($r=0.65$; $p<0.001$) to the number of items published in the period. Perhaps more striking, no single indexed publication could be identified for 42 nations—countries in which 76 million individuals under the age of 18 years currently live (Kieling & Rohde, 2012a, b).

Individual analyses per country revealed that almost half (48.19%) of the child and adolescent mental health literature in the last decade had at least one author from the United States. Other leading publishing nations were England (9.58%),

Table 16.2 Abridged recommendations for child and adolescent mental health conditions (CAMH 1–13).

Maternal mental health interventions	CAMH 1. For at-risk children, parenting interventions promoting mother-infant interactions, including psychosocial stimulation, should be offered to improve child development outcomes. To improve child development outcomes, mothers with depression or with any other mental, neurological or substance use condition should be treated using effective interventions (see recommendations for treatment of depression and other mental, neurological, or substance use conditions).
Parent skills training for behavioral disorders	CAMH 5. Parent skills training should be considered for the treatment of emotional and behavioral disorders in children age 0–7 years. The content should be culture sensitive but should not allow violation of children's basic human rights according to internationally endorsed principles.
Parent skills training for developmental disorders	CAMH 6. Parent skills training should be considered in the management of children with intellectual disabilities and pervasive developmental disorders (including autism). Such training should use culturally appropriate training material.
Child abuse	CAMH 2. Non-specialized health care facilities should consider home visiting and offer parent education to prevent child abuse, especially among at-risk individuals and families. They should also collaborate with school-based "sexual abuse prevention" programmes where available.
Intellectual disabilities	CAMH 3. Non-specialized health care provides should consider assessment and regular monitoring of children suspected of intellectual and other developmental delays by brief, locally validated questionnaires. Clinical assessment under the supervision of specialists to identify common causes of these conditions should be considered. CAMH 4. Non-specialized health care provides should consider supporting, collaborating with, and facilitating referral to and from community-based rehabilitation programmes.
Behavior disorders (attention deficit hyperactivity disorder [ADHD])	CAMH 7. Non-specialized health care providers at the secondary level should consider initiating parent education/training before starting medication for a child who has been diagnosed as suffering from ADHD. Initial interventions may include cognitive behavioral therapy (CBT) and social skills training if feasible. Methylphenidate may be considered, when available, after a careful assessment of the child, preferably in consultation with the relevant specialist and taking into consideration the preferences of parents and children.
Pharmacological interventions for children with disruptive behavior disorders or conduct disorder or oppositional defiant disorder	CAMH 8. Pharmacological interventions (such as methylphenidate, lithium, carbamazepine, and risperidone) should not be offered by nonspecialized health care providers to treat disruptive behavior disorders (DBD), conduct disorder (CD), oppositional defiant disorder (ODD), and comorbid ADHD. For these conditions, the patients should be referred to a specialist before prescribing any medicines.
Somatoform disorders	CAMH 9. Pharmacological interventions should not be considered by nonspecialized health care providers. Brief psychological interventions, including CBT, should be considered to treat somatoform disorders in children, if adequate training and supervision by specialists can be made available.
Antidepressants for children with depression	CAMH 10. Antidepressants should not be used for the treatment of children 6–12 years of age with depressive episode/disorder in nonspecialist setting.
Antidepressants for adolescents with depression	CAMH 11. Fluoxetine, but not tricyclic antidepressants (TCA) or other selective serotonin reuptake inhibitors (SSRI), may be considered as one possible treatment in nonspecialist settings of adolescents with depressive episodes. Adolescents on fluoxetine should be monitored closely for suicide ideas/behavior. Support and supervision from a mental health specialist should be obtained, if available.
Pharmacological interventions for anxiety disorders in children and adolescents	CAMH 12. Pharmacological interventions should not be considered in children and adolescents with anxiety disorders in nonspecialist settings.
Behavior change techniques for promoting mental health	CAMH 13. Non-specialized health care facilities should encourage and collaborate with school-based life skills education, if feasible, to promote mental health in children and adolescents.

Figure 16.2 The 10/90 divide in research into treatment for childhood and adolescence mental health disorders (2001–2010). *Source:* Extracted from Kieling *et al.* (2011).

Canada (6.45%), Germany (6.29%), and Australia (5.08%). The LMIC with the highest representation were Turkey (1.64%; ranked 12th), China (1.53%; 14th), and Brazil (1.42%; 15th). Trend analyses suggest that this scenario might be changing: over the 2002–2011 period, the relative proportion of authorships from the United States decreased 26%, whereas leading LMIC exhibited a growing contribution: Turkey increased its share by 136%; China, 108%; and Brazil, 86% (Kieling & Rohde, 2012a, b). This scenario calls for a need to divert research resources and talent to LMIC.

Services

Integration of child mental health to systems of care imposes a set of challenges, such as cultural adaptation of strategies from one context to another; intersectorial collaboration; identification and inclusion of high risk groups (e.g., children who dropped out of school); cost-effectiveness determination (Jordans *et al.*, 2010). Collaboration with pediatric and primary care services might leverage benefits both to mental health and to general health outcomes.

Despite the burden imposed by mental health problems to children and adolescents, most countries do not provide satisfactory care to those in need (Belfer & Saxena, 2006). The Atlas

of Child and Adolescent Mental Health Resources included data for 66 countries, showing that less than a third of them had a specific entity responsible for child mental health promotion. Also, very few countries reported having an adequate and permanent budget for such programs. A more recent survey performed in 42 LMIC used a structured instrument developed by the WHO to assess key components of mental health systems. Unfortunately, findings confirmed the inadequacy of services to address mental health problems of children and adolescents, as well as the lack of professional training at multiple levels (Morris *et al.*, 2011).

Many factors are associated with the use of mental health services by children and adolescents, and their identification is crucial for planning. A systematic review of literature identified 57 studies investigating mental health services in community and school-based samples—however, with scarce data from LMIC (Graeff-Martins, 2010). Service utilization ranged from 2.2% to 63.0%, with lower rates associated with younger age and lack of impairment associated with symptomatology. Four reports also estimated the proportion of youth requiring but not receiving treatment (a measure of unmet need), with coverage rates varying between 17.1% and 87.1% (Flisher *et al.*, 1997; Goodman *et al.*, 1997; Kataoka *et al.*, 2002;

Sturm *et al.*, 2003). Notably, no quality or outcome assessment can be determined from these figures, as they only represent the proportion of children and adolescents having any contact with services.

Promising strategies to improve access to care include investments in gatekeepers such as parents, teachers, general practitioners or pediatricians, as even if children and adolescents do not reach specialized services, they are usually in contact with such professionals. Easy to read manuals and guides with culturally adapted strategies for management of childhood mental disorders in the nonspecialist primary care (Eapen *et al.*, 2012) and school settings (Patel *et al.*, 2013) have been recently published which can be a useful resource for practitioners intending to develop services in such settings.

Other innovative strategies to overcome obstacles in mental health promotion is the use of telemedicine or telepsychiatry, enhancing the interaction between multiple professionals in the community with specialists, allowing for discussion and supervision of complex clinical cases. One example of such initiative is currently being implemented in Brazil where specialists at the University of São Paulo supervise primary care physicians from the North and the Northeast, poorer and underserved regions of the country (Lowenthal, personal communication). The majority of these strategies, however, need to be rigorously tested (see Chapter 13). Also importantly, identification and intervention strategies should ideally be interconnected, in order to avoid a situation in which diagnosis is made but treatment is not available.

Training

In addition to concerted efforts to garner investments for the development of youth mental health services, innovative approaches will be needed to maximize the limited human resources in LMIC. The demand for training in global health today is a widespread phenomenon in HIC (Johnson *et al.*, 2012), and has also presented innovative initiatives from LMIC (Kerry *et al.*, 2011). A recent survey of the Consortium of Universities for Global Health, for example, found that the number of global health programs more than quadrupled in North America in recent years, going from eight to more than 40 between 2003 and 2009 (Merson & Page, 2008). In the UK, curriculum guidelines have been launched to define a set of basic skills that medical students should possess in relation to global health (Johnson *et al.*, 2012). Clinicians and researchers from LMIC can also benefit more on collaboration with their counterparts from other LMIC and not only from HIC. This is relevant, given the fact that many LMIC have similar problems and similar resources, together with a pressing need to improve local capacity.

Efforts need to be tailored to meet the specific needs of LMIC populations while considering local availability of resources. Although the role of child and adolescent psychiatrists and psychologists is essential, in many countries specialists may only be available in major urban centers. Nonspecialists, therefore,

may help fill this void, especially in the identification of mental health problems, making appropriate referrals and providing the support system that patients need. Increasingly, innovations in training and supervision models which involve redistribution of roles so that the more specialized personnel train and supervise large numbers of nonspecialists to deliver many of the interventions previously delivered by specialists (often referred to as Task-Shifting), are seen as key to meeting the human resource deficit in mental health (Murray *et al.*, 2011; Patel *et al.*, 2011a, b; Kazdin *et al.*, 2013).

Although key initiatives from global agents can offer research-based guidance on intervention strategies, the appropriate implementation of mental health services involves the recognition of local demands and, possibly, international collaboration among LMIC (Hamoda & Belfer (2010)). In addition to collaborations with the health sector, strategies such as school-based interventions represent encouraging approaches as education receives increasing investments in many LMIC; joint enterprise can also be developed with programs such as nutritional and antenatal care.

Coordinated efforts for training multidisciplinary providers for child and adolescent mental health are required to foster the development of the next generation of clinicians and researchers. Presence of local training capacity and the development of mechanisms to attract back LMIC professionals who underwent training in HIC may help limit the brain drain phenomenon. If professionals from LMIC who have immigrated to HIC cannot return, their expertise may still be valuable as consultants for program development in their home countries. Training programs in HIC planning to train professionals from LMIC should be sensitive to teaching skills that are applicable in LMIC (e.g., advanced psychopharmacology training might have limited relevance if basic drugs are not available in the country of origin). Other alternatives for LMIC collaboration include sharing training resources and expertise among countries in close proximity (Hamoda & Belfer (2010)).

The establishment of collaborative networks is also of extreme value, and can be achieved with or without the involvement of international professional organizations. An initiative that has shown encouraging results in the promotion of mental health worldwide is the Movement for Global Mental Health (MGMH) (Lancet, 2008). It is a coalition of individuals and institutions committed to collective actions to reduce the treatment gap for people with mental disorders. The MGMH promotes their actions based on two principles: evidence of effectiveness of treatment and human rights of people with mental disorders. The initiative seeks inspiration from successful experiences, such as the movement for the care of HIV-infected people in LMIC (Eaton & Patel, 2009; Patel *et al.*, 2011a, b).

The development of courses and mentorship programs can benefit further from longitudinal involvement between countries, allowing a better appreciation of the unique challenges that each country imposes and thus establishing more meaningful collaborations. In another promising initiative, multiple

professional child and adolescent mental health organizations (including the International Association for Adolescent Psychiatry and Psychology, the International Association for Child and Adolescent Psychiatry and Allied Professions, the International Association for Child Mental Health in Schools, the World Association for Infant Mental Health, and the World Federation for Mental Health) have recently partnered in a global consortium to advance education and advocacy in the field of child mental health.

Future perspectives

Despite seemingly overwhelming challenges and limited resources, the field of global child mental health now faces a time of tremendous opportunities. While mental, neurologic, and substance-use disorders are among the most disabling conditions, global partnerships have sprouted, drawing attention to the unmet needs of child mental health worldwide. The greatest challenge ahead is to build on these partnerships to create sustainable, reliable, and cost-effective mental health services in resource-limited settings. Advancements in clinical, research, and training efforts in these underprivileged contexts are needed to answer critical questions through evidence-based research, reduce the treatment gap and the burden of mental health disorders.

Professionals in HIC can contribute to the developments in global child mental health. Research and capacity building of colleagues are two such arenas where the scope for collaboration is wide. Importantly, much can also be learnt from the experiences of professionals working in such settings—task-shifting strategies, innovative models of training and supervision, and the use of mobile phone and information technology to provide both service and training/supervision at a distance—are examples of developments which could apply to high income settings also.

CHAPTER 17

Prevention of mental disorders and promotion of competence

Mark T. Greenberg¹ and Nathaniel R. Riggs²

¹Prevention Research Center for the Promotion of Human Development, Pennsylvania State University, University Park, PA, USA

²Department of Human Development and Family Studies, Colorado State University, CO, USA

This chapter covers the broad area of prevention science, with a focus on universal and selective prevention. While space limitations prevent a comprehensive review of mental health prevention and promotion, we have selected issues and challenges that affect both researchers and practitioners. We include brief descriptions of a number of tested, effective prevention programs focused on childhood and adolescence and refer the reader to other sources for greater detail. The chapter is divided into sections on (1) epidemiology and rationale for preventive interventions, (2) the role of developmental theory in prevention and promotion, (3) defining prevention and its levels, (4) empirical advances of prevention research on mental health problems of children, (5) key issues in current and future prevention research, and (6) issues regarding dissemination, implementation, and sustainability. We conclude with recommendations to deal with the global challenges faced by research and practice in implementing effective preventive interventions.

Epidemiology and the rationale for preventive interventions

Prevention of mental, emotional, and behavioral disorders (MEBDs) in childhood and adolescence is a key avenue for improving public health and is also central to reducing morbidity from numerous related conditions. This is not only because childhood MEBD problems are predictive of adult mental health and substance use disorders but they also serve as risk factors for many other poor health outcomes in adolescence and adulthood. Mental health disorders account for 13% of the total disease burden worldwide (World Health Organization, 2009). By 2030, it is estimated that depression will be second, to HIV/AIDS, in global disease burden. In low- and middle-income (LAMI) countries, depression contributes

almost as much disease burden as malaria (World Health Organization, 2006). The rates of mental disorders increase across childhood and adolescence with one in five US adolescents reporting mental health problems (Knopf *et al.*, 2008). A striking 50% of adult mental disorders have an onset during or before adolescence (Belfer, 2008); thus, preventive models in childhood are key to reducing the burden of disorder.

The role of developmental theory in the prevention of MEBDs

One hallmark of prevention science is that it is steeped in developmental theory, which spans and integrates related fields including public health, epidemiology, neuroscience, behavioral genetics, and developmental psychopathology (Cicchetti & Cohen, 1995; Ialongo *et al.*, 2006; Bradshaw *et al.*, 2012). Developmental theory is conceived broadly to include multilevel social ecological and systems science perspectives, which incorporate layered contexts interacting in dynamic ways to influence risk and resilience (Bronfenbrenner, 1995; Green, 2006). This richness in theoretical breadth and depth provides a powerful framework for understanding the etiology of MEBDs and serves as the basis for conceptualizing, designing, and implementing preventive interventions that target their theoretically and empirically supported risk and protective factors. Risk factors increase the likelihood of MEBDs and can be characterized into one of six domains: child (e.g., self-regulation problems), family (e.g., the quality of parent-child attachment), peer (isolation), demographic (e.g., family income), school (school climate), and community/policy (e.g., neighborhood poverty and crime rates) (Coie *et al.*, 1993; Fagan *et al.*, 2007). It is clear that children living in poverty are at greatest risk for MEBDS (Yoshikawa *et al.*, 2012). Risk factors often co-occur and current theory

and research have resulted in several observations regarding the relation of risk factors to mental health problems. First, due to the complex nature of human development, it is likely that few mental health disorders are due to a single cause, or risk factor, residing in the child alone (Rutter, 1982). Rather, the development of mental health problems is often the result of multiple accumulated risks across time and contexts, potentially exhibiting nonlinear (i.e., exponential) relationship with psychopathology (Sameroff *et al.*, 1987). Second, not all children who experience any given risk factor, or set of risk factors, will develop adjustment problems, suggesting that children vary in their resilience in the face of adversity (see Chapter 27). Third, developmental epidemiology findings indicate multiple pathways to most psychological disorders; different combinations of risk factors may lead to the same disorder, and rarely are risk factors disorder-specific (Greenberg *et al.*, 1993). Thus, prevention efforts that focus on risk reduction of multiple interacting risk factors may have direct effects on diverse outcomes (Coie *et al.*, 1993).

The role of protective factors

Protective factors reduce the likelihood of maladaptive outcomes under conditions of risk and thus build resilience in particular contexts. Less is known about protective factors and their operation (Rutter 1979; Losel & Farrington, 2012), but they include domains operating at the level of the child (e.g., social-cognitive skills), family (e.g., parental warmth and monitoring), peer (peers with prosocial values), demographic (family structure), school (school quality), and community/policy (neighborhood social capital). By specifying links between protective factors, positive outcomes, and reduced problem behaviors, prevention researchers may more successfully identify relevant targets for intervention (Coie *et al.*, 1993; Fagan *et al.*, 2007) and nurture environments central to positive mental health and averting mental illness (Biglan *et al.*, 2012). It should be noted that although much of the theory regarding risk and protective factors occurs at the community level. There has been little investigation of the assumptions underlying this model (Feinberg, 2012) and much of the research on risk and protective factors has been correlational, not causal.

Developmental neuroscience and genetics

Advances in developmental neuroscience have recently advanced traditional theories of prevention science. Developmental neuroscience research has demonstrated the importance of the executive attention systems and executive function (EF) (Blair, 2002). There has been an enormous expansion of knowledge regarding both the development of EF skills and the growth and differentiation of the prefrontal area of the brain. Subsequently, there has been progress on the development of curricula and training programs to promote self-regulation, and a few programs have focused directly on developing EF skills (Davidson *et al.*, 2003; Riggs *et al.*, 2006; Diamond & Lee, 2011; Greenberg & Harris, 2011).

The growing field of developmental genetics has similarly altered models of developmental processes (Jaffee & Price, 2007). Recently, developmental models have focused on the issue of differential susceptibility to environments, with preventive interventions being a specific type of environment (Ellis *et al.*, 2011). This has heralded the initiation of research to examine Gene X Preventive Treatment interaction effects that might demonstrate that genetic endowment may lead to differential outcomes from interventions. Brody *et al.* (2014) provide one example showing that African American male teens with a *DRD4* gene variant with 7 or more repeats who received a family intervention model were more likely to show lower rates of substance use 2 years after intervention.

Promotion of competence

New and complementary models for the prevention of mental health problems also include strength-based models such as social-emotional learning (SEL) and positive youth development. For example, the Collaborative for Academic and Social-Emotional Learning (CASEL) approach to preventing mental health problems is to promote self-regulation, self-awareness, social awareness, positive peer relationships, and responsible decision-making as precursors to social-emotional competence (CASEL, 2003). Recent research shows that proficiency in each of these five domains of social competence is related to positive academic, behavioral, and mental health outcomes (Durlak *et al.*, 2011).

The specification of intervention goals is an important component of preventive intervention. Although these goals may include the prevention of difficulties (e.g., absence of psychopathology), they also involve the promotion of healthy outcomes and the enhancement of competency as mediators (e.g., effective social problem-solving mediating reduction in delinquency). This requires an understanding of how risk and protective factors contribute to outcomes, and the identification of competencies that mediate intervention outcomes.

Defining prevention

Levels of prevention

Prevention programs can take a number of forms depending upon factors such as community need and capacity. The Institute of Medicine placed preventive interventions within a broader mental health intervention framework that differentiates prevention from treatment (Institute of Medicine, 2009). Within prevention, programs can vary in terms of reach and focus.

Universal interventions target all children, are relatively low in cost, attempt to reduce a variety of risk factors, and promote a broad range of protective factors. Three common foci of school-based universal interventions are improvements to school structure (e.g., organizational features/rules), teacher's classroom management, and curricula that teach new social-emotional skills (CASEL, 2003). Common foci

of universal family programs are parenting skills including communication, responsivity, management, and monitoring of child behavior. Advantages of universal programs are that they (a) contribute to adaptive coping/resilience across an array of experiences and settings; (b) are positive and provided independent of risk status, and therefore nonstigmatizing; and (c) reduce or prevent multiple behavior problems which share overlapping risk factors (Greenberg *et al.*, 2001).

Selective interventions are those that are delivered to a class of families or children because their characteristics place them at risk for later problems. There are two broad classes of selective interventions. The first group is based on risk characteristics of the child, family, or community (e.g., poverty, the children of parents who are depressed, and children with social skills difficulties). The second type of selective intervention is for children or families who have experienced a stress-triggered event that increases their risk for maladjustment (e.g., divorce, loss of a parent through death, other traumas, moving to a new school) (Wolchik *et al.*, 2007). In both instances, no child may yet have difficulties, but the circumstances in which children find themselves create risk. Selective interventions usually involve specialized services such as group interventions (Lochman *et al.*, 2012), that teach social emotional skills, social information processing, and decision-making. A major advantage of selective programs is that effort and resources will be spent on children and youth at greatest risk for developing mental health problems. Thus, selective interventions may provide greater conceptual precision, intensity, and focus for children at relatively high risk.

Indicated prevention is directed at children or families that are already showing substantial and sometimes even diagnostic levels of difficulty (see Chapters 36 and 42). These programs usually occur after a child has had substantial difficulties (e.g., have received psychiatric diagnoses or have been arrested). Such programs are intensive and expensive, but may be cost-effective given the high-cost and long-term effects of such experiences (Lee *et al.*, 2012). As this chapter is focused on universal and selective models, the reader is referred to other sources for further review (Vitaro & Tremblay, 2008; Greenberg & Lippold, 2013).

Universal and selective interventions may employ multiple components that target school, family, and community factors. Given their extra cost, multicomponent interventions are more often utilized with selective interventions, or with universal models in high-risk neighborhoods or schools. Universal programs are likely to be most effective when implemented as part of a comprehensive, potentially tiered, approach to prevention (Greenberg *et al.*, 2001), an example of which is the Seattle Social Development Project (Hawkins *et al.*, 2005).

A relative advantage of universal prevention is that selective and indicated approaches are not sensitive to a large percentage of MEBD that develops later in life. Durlak (1995) points out that if only 8% of well-adjusted children go on to have serious adjustment problems as adults (as opposed to 30% of

clinically dysfunctional children), the well-adjusted children will represent 50% more of the population of maladjusted adults. This follows Rose's maxim that "a large number of people exposed to a small risk may generate many more cases than a small number exposed to a high risk." It may then be beneficial to provide universal preventive interventions regardless of the low prevalence rate of childhood psychopathology (Rose, 1985). Thus, when dealing with a common and costly disorder such as depression or conduct disorder, there may be justification for preventive efforts that are universal and provided at the population level (Merry & Spence, 2007; Shamblen & Derzon, 2009).

However, there are also "trade-offs" between universal and targeted (indicated or selective) approaches (Offord *et al.*, 1998). A potential disadvantage of universal programs is that if used in contexts with low prevalence of psychopathology, substantial effort will be spent on children who may not develop mental health problems. Further, because of relatively low dosage, universal intervention might not provide sufficient duration or intensity to alter pathways of children at most risk. Offord *et al.* (1998) also raises the question of whether universal programs have the greatest impact on lowest risk children, though some findings contradict this theory by demonstrating stronger effects for more at-risk subgroups (Kellam *et al.*, 2008; Spoth *et al.*, 2013a).

The implementation of universal interventions in schools also poses challenges (see Chapter 42). First, they require approval of schools that often appear overburdened with other priorities. They require multiple levels of approval from administrators, community partners, and local authorities. In general, universal interventions are likely to be most effective when they have sufficient duration and intensity, target the development of protective factors related to multiple disorders, or target problems with high prevalence (e.g., bullying, early alcohol use). Similarly, universal family-based programs face considerable challenges in effectively recruiting families to participate (Spoth *et al.*, 2013b).

Empirical advances in prevention research with children and families

The past two decades have brought clear progress and a stronger empirical base to the field of prevention (Institute of Medicine, 2009; Catalano *et al.*, 2012). Controlled trials over the past two decades have identified effective prevention programs that can reduce risk, increase protection, and reduce MEBDs. There are now a considerable number of broad reviews of evidence-based interventions (EBIs), classroom- and family-based curricula that have been shown to reduce mental health symptoms including anxiety, depression, antisocial behavior, and aggression (Greenberg *et al.*, 2001; Adi *et al.*, 2007; Hoagwood, *et al.*, 2007; Tenant *et al.*, 2007; Wilson & Lipsey, 2007; Durlak *et al.*, 2011; Sandler *et al.*, 2011; Henggeler & Sheidow, 2012; Furlong *et al.*, 2013). Program reviews are now widely available

on a number of Internet sites; those with the most rigorous inclusion criteria are Blueprints for Healthy Youth Development (www.colorado.edu/cspv/blueprints), the Cochrane Collaboration (www.cochrane.org), and the Campbell Collaboration (www.campbellcollaboration.org). The following sections highlight successful programs included in many of these reviews. However, it should be noted that positive intervention effects are not universally found despite well-reasoned theory, fidelity of implementation, and rigorous evaluation design. Thus, the following successful programs should be viewed within the context of other prevention programs that have demonstrated effects limited to subsamples of participants or null effects on all or some MEBD outcomes (e.g., Scott *et al.*, 2010a, b).

Conduct problems and aggression

The prevention of conduct problems and aggression has dominated early prevention trials. A meta-analysis examining 249 experimental studies designed to prevent aggressive and disruptive behavior yielded significant effects (Wilson & Lipsey, 2007). When divided by type of intervention, the universal model effect size was 0.21; within these studies there were somewhat larger effects for younger children and those of lower SES. Effect size for selected and indicated interventions was 0.29; among the targeted students, those who showed greater problems showed greater improvements. In addition, behavioral strategies were more effective than cognitively oriented models. There was a significant impact of the quality of implementation on outcome with higher quality implementation related to greater effect size. The authors conclude that these effects are both statistically significant but also of practical significance and they forecast that such programs would lead to a 25–33% reduction in the base rate of aggressive problems in an average school.

A recent report from a Center for Disease Control taskforce also indicates the efficacy of universal school-based models for the prevention of violence (Hahn *et al.*, 2007). Fifty-three universal prevention studies were utilized in the meta-analysis and the median effect size was 0.15, with generally greater effect sizes with preschool and elementary school-aged children. Thus, there was substantial agreement between these two comprehensive studies that universal school-based violence prevention programs represent an important means of reducing violent and aggressive behavior in the United States as well as other countries (Adi *et al.*, 2007).

Incredible Years (IY) is an exemplary selective intervention designed to reduce child behavior problems through parent training, which focuses on improving parent competencies, parent involvement in school, and effective management of child behavior problems (see Chapter 37; Webster-Stratton & Reid, 2010). Although initially used with clinical populations, numerous studies in the United States and other countries (Brotman *et al.*, 2008; Scott *et al.*, 2010a, b; Baker-Henningham *et al.*, 2012) have shown its effectiveness in improving parenting and reducing child behavior problems with selective samples, including those at risk for maltreatment (Hurlburt *et al.*, 2013).

A second exemplary parenting model is the *Triple P Positive Parenting* program (Sanders, 2008), which employs a five-level comprehensive model using media, providing basic information, advice, and support from health workers, selective parenting groups, and treatment. One evaluation of this program employed a community level “workforce development strategy” to deliver the program across diverse family-helping agencies and showed county-wide reductions in child abuse and neglect (Prinz *et al.*, 2009). This model originated in Australia and has shown evidence of positive outcome in numerous countries (Sanders, 2008).

The *Coping Power Program* is a preventive intervention involving structured sessions for selected children and behavioral parent training groups delivered to their parenting adult(s). The program is delivered at schools in small groups with at-risk children in the late elementary school and early middle school years (Lochman, *et al.*, 2012). In most studies it has shown an impact on reducing conduct problems as well as reducing risk for substance use.

Depression

There has been a dramatic increase in the development and evaluation of both universal and targeted depression prevention models during the past decade. Although meta-analyses show inconsistency in findings, few follow-ups from universal models, and a need for further replication in school settings, in general the results show substantial effects of selective programs; however, effects vary by population and there is a need for further replication in school settings (Horowitz & Garber, 2006; Merry & Spence, 2007; Stice *et al.*, 2009; Caeleir & Christensen, 2010). Due to the absence of the need for screening, and the potential benefits of nondepressed peers as models, universal programs also show promise. One recent universal prevention study with US high school students illustrates that both cognitive models and interpersonal models show overall effectiveness compared to a control sample, and that students with higher pretest depression scores had the greatest reduction from intervention (Horowitz *et al.*, 2007). In contrast, a large-scale universal trial of *Beyond Blue* involving 25 secondary schools across Australia showed no effects and investigators note the difficulties in maintaining implementation quality across school settings (Sawyer *et al.*, 2010).

The *Penn Resiliency Program* (PRP; Gillham *et al.* 2008) has been one of the most widely researched depression prevention programs. A meta-analysis of 17 studies showed consistent small, but significant effects at 6- and 12-month follow-up in both universal and selective implementations (Brunwasser *et al.*, 2009). Arnarson and Craighead (2011) provide an exemplar universal study involving Icelandic children at risk for depression and showing significant reduction in the first depressive episode through one year of follow-up.

Anxiety

Anxiety disorders are the most frequent psychiatric disorders in adolescents, yet only recently have they been a focus for

preventive interventions. Although there are relatively few studies that have examined preventive interventions for anxiety disorders, these programs appear quite promising (Neil & Christensen, 2009; Lau & Rapee, 2011). Both universal and indicated interventions have been conducted with populations from preschoolers through early teens and have shown significant reductions at post-test, with some effects maintained as long as two to three years after intervention. Initial studies have in some cases shown the largest impact on girls (although impact on boys is also reported) and on children around ages 11 and 12. Most of these studies have been conducted in Australia and require replication in other countries. Teubert and Piquart (2011) conducted a recent meta-analysis of 65 trials. They reported small but significant effects on anxiety at posttest (effect size; symptoms = 0.22, diagnosis = 0.23) and follow-up (effect size; symptoms = 0.19, diagnosis = 0.32). Intervention effects at posttest varied by type of prevention. As expected, selective programs showed larger effect sizes than universal programs. As with depression prevention, there is a need for longer term follow-up of outcomes.

The *FRIENDS* program is an exemplar cognitive-behavioral universal anxiety prevention program used in school contexts (Barrett & Turner, 2011). The program involves 10 in-school sessions, 2 booster sessions, and information for parents. Across studies, the outcome from *FRIENDS* typically indicates a significant decrease in anxiety symptoms. Most studies in Australia have shown significant reduction in anxiety symptoms. However, there have been a few recent nonreplications in other countries (Lau & Rapee, 2011).

Early substance use

Spoth *et al.* (2008) reviewed 127 reports of prevention studies with alcohol-specific outcome measures. Most studies were in schools, taught social, cognitive, and peer resistance skills and fell into three age groups (below 10, 10–15, 16–20+). They classified interventions as “most promising evidence,” “mixed or emerging evidence,” and “insufficient or no evidence of impact.” Twelve interventions met criteria for “most promising” and 28 met criteria for “mixed or emerging.” The review indicated the need for greater emphasis on early teens, young adults not attending college, and non-majority populations, the need for longer longitudinal follow-up, replication studies, and dissemination research. Other reviews have shown that interventions in early adolescence can reduce the rates of alcohol, marijuana, other illegal drugs, and misuse of prescription drugs.

Life Skills Training is a 15-session school-based program with additional booster sessions that has been widely studied and implemented (Botvin *et al.*, 2006). When implemented with high quality it has been shown to reduce early use of alcohol, tobacco, and other drugs and has shown effects up to 5 years after intervention.

Unplugged is a universal prevention program tested in a European trial involving seven countries. Similar to LST, it is a 12 hour teacher-led program which includes interpersonal life

skills through a social-cognition approach. Persisting beneficial program effects were found for past 30-day episodes of drunkenness and for frequent cannabis use (Faggiano *et al.*, 2010).

The *Strengthening Families Program: For Parents and Youth 10–14* (SFP 10–14) is a seven-session universal family-focused program that enhances parenting skills—specifically nurturance, limit setting, and communication, and youth substance refusal. SFP has shown effects on alcohol, tobacco, and illicit substance use up to 9 years after intervention (age 21) and its effects are mediated by improvements in the parent–youth relationship (Spoth *et al.*, 2012).

Promotion of social and emotional competence

Two recent meta-analyses have examined the effectiveness of universal school-based interventions (Durlak *et al.*, 2011; Sklad *et al.*, 2012). Durlak’s analysis of US programs indicated that SEL (social and emotional learning) interventions have a substantial impact (effects sizes 0.15–0.35) on a variety of outcomes including aggression and disruption, social and emotional competence, school bonding, prosocial norms, disciplinary referrals, emotional distress, and academic achievement. Sklad’s analysis included 25% of programs outside the United States and showed somewhat higher effect sizes at posttest and follow-up. It should be noted that few interventions that focus on promoting positive development or citizenship have been evaluated.

The *PATHS Curriculum* is a widely studied universal SEL program for preschool and elementary school-aged children. It is provided by classroom teachers and focuses on emotional awareness, self-control and social problem-solving. A series of RCTs have shown significant, modest improvements in prosocial behavior and reductions in aggressive/disruptive behaviors, and depressive symptoms as well as improvements in executive functions and classroom atmosphere (Kusché & Greenberg, 2012).

Event-triggered prevention: the prevention of trauma

A variety of selective prevention programs have been developed to support resilience in children who have experienced events that place them at risk (e.g., divorce, death of a parent, and trauma resulting from war or refugee status—see Chapter 59). Although these programs have different foci and techniques, results are quite promising. For example, studies have shown reduction in PTSD symptoms and depression in Israeli children subject to terrorist attacks (Gelkopf & Berger, 2009), Israeli students subject to ongoing rocket attacks (Wolmer *et al.*, 2011; Berger *et al.*, 2012), Russian children taken hostage in a school siege (Vetter *et al.*, 2010), and US children who experienced a potentially traumatic event (Berkowitz *et al.*, 2011). On the other hand, mixed results were found in a study of children experiencing war exposure in Sri Lanka (Tol *et al.*, 2012). Given the plight of refugee children in many countries, there is a need to develop further interventions to prevent and/or reduce the effects of PTSD (Pacione *et al.*, 2013; Schneider *et al.*, 2013).

The *New Beginnings Program* (NBP) (Wolchik *et al.*, 2007) is an 11-session program with the residential parent designed to improve children's coping with divorce by strengthening parenting. At six-year follow-up, youth in the NBP had lower rates of diagnosed mental disorder, less substance use and risky sexual behavior, and higher school grades.

Birth to five: early prevention

During the past three decades attention has focused on the effects of early prevention for children living in poverty or other at-risk circumstances (Manning *et al.*, 2010). Broadly, three types of programs have been effective in reducing early maltreatment and other early outcomes related to later mental disorders. First, high-quality home visiting programs beginning prenatally or after birth have demonstrated long-term impacts on both children and parents (MacMillan *et al.*, 2009; Olds, 2010). Second, preschool parenting interventions have reduced conduct problems both in group (Webster-Stratton & Reid, 2010) and individual contexts (Toth & Gravener, 2012) utilizing both attachment-focused and cognitive-behavioral orientations (Furlong *et al.*, 2013). Third, quality preschool experience has lowered risk for MEBDs and promoted healthy functioning into adulthood (Reynolds *et al.*, 2010). All three types of interventions have been found to have a high benefit-to-cost ratio (Conti & Heckman, 2012; Lee *et al.*, 2012).

The *Nurse Family Partnership* is a nurse-led home visiting intervention for first-time mothers at risk as a result of poverty and other risk factors (Olds, 2010). It has been tested in three RCTs in the United States. The intervention begins prenatally and ends at age 2 with a focus on both mother's life course and the mother-child relationship. This intensive intervention has resulted in lower rates of neglect and abuse, and lower rates of drug and alcohol use and arrests for the children in the transition to adulthood. In one trial, visited children showed higher school achievement at age 9.

Family Foundations is a universal eight-session intervention for expectant parents delivered through before and after birth by childbirth education departments (Feinberg *et al.*, 2010). The program prepares couples for parenthood by fostering attitudes and skills related to positive parenting teamwork (called "coparenting"). Through age 3, effects include reduced parental stress, depression, and harsh parenting, and improved child social competence. Significant effects were found for boys on child behavior problems and couple relationship quality.

Prevention in lower and lower-middle income countries

Mental health services for children in most lower and middle income countries (LAMIC) are scarce (see Chapters 16 and 44). An essential question is whether preventive interventions developed in Western technological societies will be transferable (albeit with modifications) to LAMI countries. During the past decade there has been a substantial rise in the number of preventive interventions focused on mental health in such countries

as Tanzania (Hermenau *et al.*, 2012), Iran (Oveisi *et al.*, 2010), Mauritius (Rivet-Duval *et al.*, 2011), and Romania (Stefan & Miclea, 2013). Mejia *et al.* (2012) provide a thoughtful discussion of the numerous issues in program modification and implementation. Future research should focus on the adaptation of existing programs and the development of indigenous, local programs.

Key issues in current prevention research

Researchers have paid increasing attention to improving methodology and most studies now use randomized designs that enhance the credibility of the outcomes. Nevertheless, the field has significant gaps that need to be addressed.

Limited longitudinal studies

One important issue is the collection of data over extended periods of time to track the longitudinal effects at different stages of development. This is especially important for universal studies as few children in a whole population have, or are at risk for, a disorder. Thus, the follow-up period should be sufficiently long in order to "allow" the control populations to develop symptoms/disorders. For example, if studies of the immunization of polio only provided a 6-month follow-up, it is likely that one would conclude that immunization was ineffective. One would need to follow the control (nonimmunized) population long enough for a substantial number of cases to manifest in order to document the vaccine effectiveness.

The need for independent replication studies

There has been substantial controversy regarding potential publication bias and the lack of independent replication of programs and policies (Holder, 2009; Axford & Morpeth, 2013). Surely, the concern regarding the potential bias introduced by studies that are not independent of the developer is a key issue (Eisner, 2009; Olds, 2009) and there is a need to verify findings in independent trials.

Limited long-term economic assessments have been conducted to date; however, existing cost-benefit analyses clearly indicate that EBIs (evidence-based intervention) can be cost effective (Lee *et al.*, 2012). This has yet to lead to a large-scale shift in policy to support widespread EBI dissemination and implementation. It is notable that few evaluations have assessed the costs and benefits of building the infrastructure necessary to successfully install and sustain large-scale prevention efforts (Crowley *et al.*, 2012). It is more likely that when research is conducted within actual service settings capable of sustainability, key factors relevant to economic outcomes will be included in evaluations. Given their relatively low cost, such analyses could be particularly important for universal and selective interventions.

Limited study of factors that moderate effects

It is essential to understand the factors that may moderate (i.e., increase or decrease) the magnitude of intervention effect.

This is especially important for universal interventions that target all members of a certain population. Is the intervention equally effective for all members of the population, regardless of their level of risk for mental health problems? Such analyses are necessary as it is unlikely that intervention effects are uniform for participants (Brown & Liao, 1999; Scott & O'Connor, 2012; Brody *et al.*, 2014).

Consistent standards for evidence and research reporting

Consistent standards for evaluating interventions, conducting replication trials, and reporting results are needed (Flay *et al.*, 2005). Although no single method fits all interventions, standards should include study design components such as randomization (where feasible); using multiple, unbiased reporters; examining follow-up effects; and fully reporting outcome data. Accordingly, an intervention could be considered efficacious if it produced consistent and statistically significant findings in high-quality, independent studies and the findings have public health significance. To be considered disseminable, an intervention also would provide manuals or training programs that allow it to be implemented by third parties and evaluated under real-world conditions (Flay *et al.*, 2005). To date, few intervention research programs meet these standards. The UN Office on Drug and Crime has recommended international standards for drug abuse prevention and similar standards are needed in mental health (UNODC, 2013).

Need for improved standards concerning intervention replications and cultural adaptations

When replication studies are conducted, standards are needed for judging when a study is truly a replication or when substantial program modifications would mean the study no longer qualifies as a replication (Valentine *et al.*, 2011). As preventive interventions are transported across cultures and contexts, there is a need to adapt and modify the interventions, at least in terms of their surface structure (Moore *et al.*, 2013). Conceptual and practical guidelines for the cultural adaptations are available and there are numerous examples of such adaptations (Castro *et al.*, 2004; Ferrer-Wreder *et al.*, 2012; Colby *et al.*, 2013). Studies are needed to examine the effects of systematic variations of the original intervention to understand the influence of culture and context and its generalizability.

Metrics for reporting and levels of prevention

Clear metrics are needed to report outcomes to the public and policy makers, and this may differ depending upon the level of prevention. Effect size may be the best metric for selective interventions, where participants begin with greater risk or symptoms and thus show greater change. However, it may be a poor metric for universal interventions where a large percentage of the population begins without symptoms and thus it is unlikely to show change. In most cases, it is only in the higher risk/symptom groups that larger effect sizes will be obtained (Wilson & Lipsey, 2007).

Thus, for universal interventions, other risk reduction metrics, potentially in combination with thoughtful use of effect sizes, are more appropriate (Davis *et al.*, 2003). For example, a universal depression program may reduce diagnoses from 10% to 5% of the population; thus, risk reduction would indicate a 50% reduction in prevalence. However, if 90% of the population shows no depression, the effect size for the entire population will surely be in the “small” range. Shamblen and Derzon (2009) use a population level adjustment model to illustrate the different interpretations that can be made from the same effect sizes. Thus, comparing effect sizes of selective versus universal programs to conclude which may be more effective is problematic (Horowitz & Garber, 2006).

Dissemination, implementation and sustainability; Type 2 questions

Much of the research covered is classified as Type 1 research: understanding basic developmental mechanisms and applying this research to the development, testing, and refinement of preventive interventions. As a growing number of programs have shown efficacy in controlled trials, the next stage in prevention research is studying program effectiveness under real-world conditions (Institute of Medicine, 2009) or with the use of new delivery models such as use of the Internet or telemedicine. There is also a significant gap between the availability of such preventive interventions and their widespread implementation across communities and nations (Glasgow *et al.*, 2003; Rhoades *et al.*, 2012).

Type 2 translation research investigates the complex processes and systems through which EBIs are adopted, implemented, and sustained on a large scale, as well as devising empirically driven strategies for increasing their population impact. Spoth *et al.* (2013a, b) have proposed a heuristic model, the Translation Science to Population Impact (TSci Impact) Framework, to conceptualize research and practice issues related to the four phases of pre-adoption, adoption, implementation, and sustainability.

In the preadoption phase, there are numerous issues including how information on EBIs is diffused by governments and NGOs, and understanding the communication channels used by prospective adopters. One strategy for assisting the diffusion process is to provide agencies, schools, and communities with guidelines and recommendations for choosing among EBIs. Numerous best-practice guidelines and reports have been published in the United States (e.g., Blueprints for Violence Prevention; National Registry of Evidence-based Programs and Practices (<http://www.nrepp.samhsa.gov/>), in Europe (Fundacion Marcelino Botin, 2008), and the United Kingdom (Allen, 2011). However, the lack of well-standardized criteria for selecting “model” or “effective” programs can be confusing to prospective adopters.

The selection of evidence-based prevention strategies is just the first step to achieving widespread, high-quality, and

sustained prevention programming. Once selected, adopters require expert training and technical assistance to ensure high-fidelity implementation. Adopters must ensure that they are faithfully replicating the core intervention components and ongoing monitoring and technical assistance are necessary to ensure that implementation is congruent with the core principles associated with program success (Kelly & Perkins, 2012). Finally, to achieve population-level outcomes, communities must learn how to effectively recruit interventions participants via large-scale media or marketing campaigns. Implementation challenges will inevitably occur and communities will be more successful when they increase their capacity for effective implementation and are provided with proactive technical assistance to carefully monitor program needs. A key issue in implementation is the need to adapt EBIs to create a better fit with the nature of public mental health and social service systems (Little, 2010). This requires that public systems and program developers work together to understand issues of scaling as they design, test, and implement new interventions. To achieve long-term success, organizations need to enhance their internal capacity to support preventive interventions.

As effective programs become more widely adopted, the need for strategies to enhance their long-term sustainability becomes increasingly important. Program sustainability can be threatened by many causes, including implementation challenges, loss of funding, and changes in priorities among key players. Moving from funding based on discretionary, short-term grants to more stable funding streams is a substantial challenge. Research regarding the conditions which facilitate or undermine sustainability is only beginning to emerge. A study of 67 EBIs funded in Pennsylvania found that 5 years after state funding withdrawal, 45% of programs were operating at the same or a higher level, 22% at a reduced level, and 33% were no longer operating (Tibbitts *et al.*, 2010). Other research has indicated that long-term sustainability is associated with strong levels of staff and leaders support; widespread belief in the benefits of the innovation; and a strong integration between the new innovation and the agency's mission, schedule of services, and staffing profile (Scheirer & Dearing, 2011; Greenberg & Lippold, 2013). These factors also promote the adoption and quality implementation of new programs, indicating that efforts to increase organizational capacity for prevention can increase the likelihood of widespread, high-quality, and sustained prevention programming.

Adopting public health impact-oriented models

Methods for increasing the general and specific capacity of local communities to undertake successful prevention are only now beginning to emerge. Strong collaborations between researchers, practitioners, and governments are necessary to achieve this goal. One model is to develop an intermediary organization between government and local communities to support

quality implementation and sustainability as conceptualized by Wandersman *et al.* (2008). Bumbarger and Campbell (2012) illustrate such a model from a decade-long partnership in Pennsylvania. In the United States and Europe, models have also been developed to create community-level infrastructure to facilitate prevention efforts including the Communities That Care (CTC) and The PROMoting School-community-university Partnerships to Enhance Resilience (PROSPER) models (Catalano *et al.*, 2012). CTC includes structured training workshops and proactive technical assistance to assist communities in conducting needs assessments, selecting, and implementing EBIs that address these needs. The PROSPER model seeks to increase community capacity by explicitly linking community stakeholders with land-grant university faculty and researchers that undertake prevention activities in local schools (Spoth *et al.*, 2013a). Both CTC and PROSPER have been moderately successful in enhancing community collaboration to undertake prevention activities, reducing rates of problem behaviors among youth, and sustaining prevention activities over time (Hawkins *et al.*, 2012; Spoth *et al.*, 2013a).

Conclusion

During the past two decades, prevention science has emerged as a new multidisciplinary science. Research primarily in high-income countries has demonstrated that major mental health problems can be moderately reduced through population-level preventive interventions as well as through programs that selectively intervene with children already at risk due to early behavioral risk and experience/context. However, few of these interventions have reached the status of “business as usual” in mental health or social service systems and only a small number of interventions have shown consistent outcomes. The expansion and broad use of these interventions will require changes in policy and practice, as well as further demonstrations of cost-effectiveness. New research is needed to understand for whom these interventions are most effective as well as how to modify interventions to fit cultural circumstances. Policy work is necessary to inform government officials regarding the importance of EBIs that have the potential to reduce health spending and other social costs. To create widespread adoption in LAMI countries, it is necessary to understand if there are unique risk and protective factors that might lead to new or modified interventions that better suit these contexts. Governments, agencies, schools, and local communities will vary in their capacity to incorporate EBIs into service systems and schools. A future goal of the field is to identify approaches that promote the readiness and capacity of prospective stakeholders to adopt effective interventions in a coordinated manner, implement them effectively, and sustain them over time. Such systematic process will be necessary to substantially reduce the public health burden and improve community-level well-being.

CHAPTER 18

Health economics

Martin Knapp¹ and Sara Evans-Lacko²

¹Department of Social Policy, London School of Economics and Political Science, UK

²Institute of Psychiatry, Psychology and Neuroscience, King's College London, UK

Introduction

For better or for worse, money is a key consideration in policy and practice discussions, even if it sometimes lurks just below the surface. Although the professional delivering one-to-one therapy, or prescribing a course of medication or arranging a group activity might not have to be concerned about the associated costs, further along the management chain someone will be watching expenditure levels and trying to balance the books. And while the budget holder may be focused on avoiding a financial deficit at the end of the year, someone higher up in the health, education or social services system will need to consider wider strategic options and will be looking to achieve the best value for money in the use of available resources. If a new treatment (such as a new medicine, a new mode of family therapy, or a new arrangement for care and support) is introduced—and known to be effective—budget holders will want to know whether it is affordable and worth what it costs to provide. If needs and their consequences are enduring, governments will want to know the associated long-term expenditure implications and how to contain them.

The underlying challenge common to all of these wants or concerns is scarcity: there are never enough resources to meet all of society's needs. This is the most fundamental, pervasive, durable, and indeed important justification for a better understanding of the economics of child and adolescent mental health. Scarcity is an endemic, in fact permanent feature of all health and related systems, and is the reason why choices have to be made between alternative uses of a particular resource or service. As we shall see, those choices between alternative uses give meaning to costs. Economics—and, in particular, economic evaluation—aims to provide evidence to inform both professional practice and strategic decisions about how to allocate available resources so as to get more out of them (in terms of—for example—better outcomes for children and families, or

a fairer distribution of access to, or use of services), and about the incentives needed to help achieve those allocations.

Although the primary aim of any mental health system is to alleviate symptoms so as to improve personal functioning and promote quality of life, it is increasingly recognized that pursuit of such a laudable, fundamental objective cannot proceed without regard for the economic consequences of the therapies, support arrangements or broad policy strategies put into place. Awareness of this need to improve not only the effectiveness but also the cost-effectiveness of health care (and other) interventions and actions has produced various demands for economic evidence. There are requests for measures of the overall resource or cost impact of a particular health problem, (often called *cost-of-illness* studies). There are demands for *cost-effectiveness* and similar analyses of particular treatments or policies, carried out either alongside trials or independently: these are evaluations that compare not only the outcomes of two or more different interventions but also the relative costs of achieving them. There are searches for new service and system reconfigurations that can improve the efficiency of use of available resources. And there are searches for improved incentive structures that could positively alter the ways that resources are deployed.

Health economic methods provide a powerful way to help answer questions relevant to health professionals, budget holders, and governments and can aid in decision-making. Considerations around health care decisions are always relevant, however, as the global economic context changes, decisions, preferences, and social conditions may also change. For example, during the current economic “crisis” facing a number of countries, policymakers, and budget holders may seek austerity measures aimed at reducing costs (Wahlbeck & McDaid, 2012; Knapp, 2013); however, these choices need to be made carefully within the context of changes in population mental health and social conditions, and in cognizance of the preferences of children and families. Methods such

as cost, cost-offset analyses (comparing amounts expended with amounts saved), and cost-effectiveness analyses (comparing costs and the outcomes achieved) can support better, more informed decisions about the efficient ways of allocating resources during times of economic transition. It may be that increasing investment in interventions or services to alleviate the consequences of the recession could be associated with long-term savings. In addition, during times of economic growth, economic methods can help determine the most efficient ways of scaling up services. For instance, health economic methods could be especially relevant to countries such as Brazil, Russia, India, China, and South Africa, which are experiencing rapid economic and health transitions, generating a strong economic need for timely investment to address mental disorders. Recent estimation of the resources needed compared to the resources currently available in South Africa makes the case for further investment and scaling up of child and adolescent mental health services (Lund *et al.*, 2009).

Costs in childhood

Mental health problems—if they are recognized and responded to—have cost implications. The most obvious effect will be on health service utilization, but there may be contacts with special education, social work, public housing, criminal justice, and other service-delivering agencies. Indeed, the multiplicity of contacts and services is a marked and welcome characteristic of well-developed child and adolescent mental health systems (Glied & Cuellar, 2003). If needs or problems are not appropriately treated, then there could be adverse effects on functioning, with implications for educational engagement and attainment, employment and income (in later years), as well as effects on families. A number of studies have described these costs during childhood and adolescence.

Snell *et al.* (2013) demonstrate the substantial additional health care, social care, and education costs associated with childhood psychiatric disorders and the range of sectors impacted. National annual cost estimates associated with services used by young people aged 5–15 years were derived from the British Survey of Child and Adolescent Mental Health (Meltzer *et al.*, 2000) (see Figure 18.1). In addition to showing the large magnitude of costs associated with childhood psychiatric disorders, the study emphasized the substantial impact on the education sector. The cost of care delivered by frontline education services was more than twelve times greater than that delivered by specialty mental health services; the costs of special education services were also high. Cost also differed by type of child mental health problem with higher costs being associated with children with hyperkinetic and conduct disorders, compared to children with emotional disorders.

Romeo *et al.* (2006) looked at the impact across a range of sectors, but also estimated broad implications for families and the wider economy, in this case, for children referred for severe

Figure 18.1 Health, social service and education resource use: mean cost over three-year follow-up for all children/young people with a disorder. Note: Costs can be converted from £ sterling to US\$ by dividing the £ figures by 0.681. Source: Snell *et al.*, 2013. Reproduced with permission of John Wiley & Sons.

antisocial behavior. This study found considerable nonservice costs, with almost half of the total costs being borne by the family. Mean annual cost of care was £5960 (equivalent to US\$8752 using the OECD purchasing power parity exchange rate (Organization for Economic Cooperation and Development, 2013) for which the same conversion rate is used throughout the chapter). Around this mean, costs varied by as much as a factor of more than 400, emphasizing the inherent heterogeneity in samples of children with mental health needs.

A third example points to the high and enduring costs of autistic spectrum disorder in both the United States and the UK. Integrating data from a number of studies on accommodation, medical services, nonmedical services, and out-of-pocket payments by families, combined with estimates of prevalence, Buescher *et al.* (2014) suggested that the discounted lifetime cost of someone with autism and intellectual disability were quite similar in the two countries. The study also found—similar to the evidence reported by Snell and colleagues discussed above—that high costs were borne by the education sector (specifically special education in this case), with parental productivity losses also found to be large.

What the Snell, Romeo and Buescher studies show very clearly is the breadth of economic impact across a variety of service sectors and on families, although they can only measure what is provided (in terms of service-related costs) or what impacts

are recognized (in terms of indirect costs). We shall see in the next section that if behavioral problems in childhood or adolescence are inadequately addressed, then there are also likely to be substantial long-term costs stretching into adulthood.

The extent to which the resource (cost) consequences of childhood or adolescent mental health problems fall outside the health sector will obviously depend on how that and neighboring sectors are organized and configured: different boundaries between health, social services, education, housing, and other service sectors will mean redrawing the cost map. But it will not change the fact that many young people with mental health problems have needs in multiple life domains, each of them potentially with economic ramifications. Foster and Jones (2005), for example, describe the economic implications of conduct disorder among adolescents in four US communities over a seven-year period. The cost difference between youths with and without conduct disorder was nearly \$70,000. The distribution of costs between budgets was different from that found in the UK partly because of differences in system structures.

These multiple impacts are obviously hard to measure, and much harder still to factor into decision-making. Not only does the decision-maker in, for example, the health sector need to find out the implications of their actions for other sectors, whether positive or negative, but they also have to think through the mechanisms needed to do something about them. A major problem in many systems is “silo budgeting”: resources located in specific agencies or budgets cannot easily be shifted, indeed might be rigorously protected (Glieb & Cuellar, 2003). Professional rivalry, myopic budget protection, performance assessment regimes or simply slowly churning bureaucratic processes could leave one agency unwilling or unable to devote more of its own resources in order for another agency or service to achieve savings, or for the broader system of treatment and support to achieve greater effectiveness or cost-effectiveness.

Costs continuing into adulthood

It is well known that mental health problems experienced in childhood or adolescence can have many and often serious adverse effects on psychosocial outcomes such as crime, relationships, substance misuse, and on quality of life. Many studies have traced these connections between behavioral and emotional problems in childhood and adverse experiences of various kinds in adulthood (see Chapter 1).

Mental health needs in childhood could also be associated with later physical health needs. Physical and mental comorbidities tend to cluster together and can thus lead to increased costs in childhood due particularly to increased service use (Guevara *et al.*, 2001; Nelson *et al.*, 2013). These comorbid health problems are likely to worsen in adulthood, with service costs being correspondingly higher (Naylor *et al.*, 2012), plus there could be further costs associated with lower workforce participation and higher absenteeism (Molosankwe *et al.*, 2012). Although

comorbidity seems to be the rule rather than the exception, there is a lack of research on how these comorbidities interact, the economic consequences of these disorders occurring together, and how best to evaluate the costs and outcomes of complex combinations of interventions aimed at addressing comorbid problems.

Many of the adulthood sequelae of child mental health problems and experiences will have measurable cost consequences, and while any computed monetary indicators cannot hope to represent or cover the full set of experiences of individual children and adults, they have the virtue of expressing some of these experiences in magnitudes that are readily understood by those key policy makers who hold the purse strings.

A few studies have explicitly explored the connections between childhood disorders and adulthood economic consequences. These studies demonstrate unusually high rates of utilization of health and other services (obviously with personal and societal costs), and impacts related to employment, such as not being economically active, or being active but unemployed, or being employed but frequently absent or unproductive, or working in a lower status occupation than would otherwise be expected. The employment effects will almost inevitably have impacts on earnings and could lead to individual and household poverty. Three examples can be offered.

Evidence from the Inner London Longitudinal Study

The Inner London Longitudinal Study collected data on 2281 10-year olds in 1970 and selected 228 of them for intensive study: a random 1 in 12 sample of the population and a 1 in 2 sample of children with emotional or behavioral problems (Maughan, 1989). This group was interviewed again at age 28. Neither interview set out to collect “economic” data as such, but it was possible to construct service-related costs from the information gathered (Scott *et al.* 2001). Nevertheless, the computed cost averages are undoubtedly underestimates of the full costs because the data collection did not cover all possible impacts and did not follow people continuously over time. Among the costs not measured were those associated with social work, voluntary sector service use, primary health care contacts, lost employment, divorce, undetected crime, the effects of crime on victims, the emotional impacts on other people, and other transmitted effects to other family members or children. Many of these omissions are known to be substantial (see below). Notwithstanding these missing elements, conduct disorder in childhood (which was found for the most antisocial 3% of the population studied) and conduct problems (which were found for the next 9%) led to greatly elevated costs in adulthood for a number of agencies, and especially for the criminal justice system (Figure 18.2).

The links between conduct problems and conduct disorder in childhood and service-related costs in early adulthood were further explored through multiple regression analysis, adjusting for gender, parental social class, reading age, number of primary

Figure 18.2 Costs in early adulthood from childhood conduct disorder. *Source:* Reproduced with permission of BMJ.

schools attended. A number of other factors were examined, but found not to be significant. Adjusting for those covariates, the estimated coefficient on the conduct disorder variable—the additional cost between the ages of 10 and 28 (aggregating across all 18 years) of having conduct disorder at age 10 compared to not having any antisocial behavior problems—was £40,784 (at 2004/05 prices; equivalent to US\$59,888). The additional cost of having conduct problems (those who were less severely affected by antisocial behavior—the next 9% of the group) compared to having no such problems was £17,017 (US\$24,988). Given the underdeveloped and underresourced nature of child and adolescent mental health services in the UK in the early 1970s, these cost differences might perhaps be interpreted as indicative of the economic consequences of not addressing (or only rather poorly addressing) antisocial behavior among 10-year olds.

Evidence from a British birth cohort study

The second example comes from the 1970 British birth cohort study (BCS70) and illustrates employment-related consequences of child and adolescent mental health problems. The BCS70 is a nationally representative birth cohort of 17,196 babies born in the UK during a particular week in 1970. Data were collected from young people and their families at ages 5, 10, 16, 26, 30, and 34. Knapp *et al.* (2011) looked at the links between childhood antisocial conduct, attention deficit, anxiety, and coordination problems at age 10 and employment experiences (economic inactivity, occupational status, and earnings) at age 30.

In general, mental health problems during childhood were associated with worse employment outcomes during adulthood; however, the consequences varied by gender and by type of mental health problem. Both women and men with childhood attention deficit problems had worse outcomes across all indicators (i.e., lower employment rates, worse jobs, lower earnings if employed, and lower expected earnings overall). Among individuals with anxiety problems, men had lower earnings if

employed and lower expected earnings overall. Women with childhood anxiety problems had lower expected overall earnings only. Individuals with childhood coordination problems had the fewest adverse consequences during adulthood: men with childhood coordination problems had lower expected earnings. Males with conduct problems at age 10 had an interesting pattern of mixed outcomes in adulthood. Males with childhood conduct problems were more likely to be unemployed at age 30. Unexpectedly, however, those who were employed had higher earnings and higher expected overall earnings (when taking economic inactivity into account). No such trend was evident for women with childhood conduct problems.

Other childhood social and psychosocial factors were also found to be important for later adult employment including: low cognitive attainment, living in a disadvantaged neighborhood, having a mother with higher educational qualifications, lower family income, and being looked after by a local authority (municipality).

Evidence from a 20-year follow-up of boys resident in the London Borough of Newham

D'Amico *et al.* (2014) describe the longitudinal trajectory of childhood behavior problems and their impact for a range of problems in adulthood. Eighty-three individuals were followed up from a population-based cohort of 6–7 year old boys resident in the London Borough of Newham who were attending mainstream schools (Taylor *et al.*, 1991) twenty years after baseline (participants were between the ages of 25 and 30 years at follow-up). For this study, participants were categorized into four groups based on their baseline responses: (a) hyperactivity problems only; (b) conduct problems only; (c) mixed conduct and hyperactivity problems and (d) no hyperactivity or conduct problems.

The study found that boys with baseline conduct problems had the highest costs in early adulthood, mostly because of the

contacts with the criminal justice system. Childhood conduct problems were associated with a two- to three-fold increase in costs in early adulthood. The mixed group had the highest health and social care costs, but their overall costs were lower because they had the lowest criminal justice costs. After adjusting for socio-demographic factors, the average increased costs for individuals with conduct problems only were the highest (£4033 (US\$5922)), while individuals with mixed conduct and hyperactivity problems had similar costs (£2208) to those with hyperactivity problems only (£2118). These figures are somewhat lower than those found by Scott *et al.* (2001).

Evidence of early prevention and intervention programs for young people

In 2004, Aos and colleagues (2004) were commissioned by the Washington State legislature to investigate the long-term costs and benefits of early prevention and intervention programs for young people. Specifically, they were asked to make recommendations about (a) whether prevention and early intervention programs were a good investment and (b) which programs would provide the best investment. To answer this question, they modeled the costs and benefits across seven key areas: education, crime, substance abuse, child abuse and neglect, teen pregnancy, and public assistance. Programs which performed a rigorous evaluation of at least one of the key outcomes were identified from the literature.

Importantly, the report concluded that some prevention and early intervention can provide a good return on investment to taxpayers. However, findings were mixed, with some interventions resulting in clear benefits while for others the benefits did not outweigh the costs. Thus, their findings emphasized the importance of rigorous evaluation and attention to fidelity and quality control when considering the implementation of a program.

Economic analysis showed that the highest net benefits were associated with programs for juvenile offenders, although outcomes varied widely even among effective programs (from \$1900 to \$31,200 per young person). Home visiting programs and early childhood education targeted at risk and/or low income families also provided good return on investment (\$6000 to \$17,200 for home visiting programs, and up to \$9000 for early education programs). The net benefits associated with substance abuse programs were relatively low, but were still found to be cost-effective because most programs were inexpensive. A gap was identified among programs which were effective at reducing teen pregnancy.

Impact of child maltreatment

Another example—this time from the Netherlands—is the evaluation of the long-term impact of risk factors such as child maltreatment on health-related costs, specifically, costs that arise when people are confronted with mental disorders due to health care uptake and productivity losses when staying absent from work. Data for this analysis came from Netherlands

Mental Health Survey and Incidence Study (NEMESIS) which included 5618 individuals in a large, population-based cohort. At the individual level, excess costs of child maltreatment at 1-year follow-up were between \$2610 and \$3666 when adjusting for socio-demographic factors in addition to parental anxiety and depression. At the population level, child maltreatment was associated with excess costs of between \$203 million and \$655 million per million people per year. Importantly, the study also found that certain protective factors, such as a high internal locus of control, ameliorated the onset of mental disorder and subsequently also reduced the associated economic consequences (Smit *et al.*, 2013).

Cost-offset considerations

A question that governments and other macrolevel decision-makers often want answering is whether investment in preventive measures or better treatments during (say) a child's early years will pay off in terms of reduced economic impacts in adolescence and in adulthood. This is what economists would call the *cost-offset* question: it asks about the balance between amounts expended and amounts saved.

There have been studies which have looked at the long-term cost-offsetting properties of such investments. An example comes from the United States where Foster and Connor (Foster & Connor, 2005) investigated the impact of improved community mental health services for young people on fiscal expenditures in other sectors. The study found that delivering child and adolescent mental health services as part of a system-of-care approach, while more expensive than standard services, reduced expenditure in other sectors (juvenile justice, child welfare, special education, inpatient services). Thus the reduced expenditures in other sectors partially offset the costs of improved community mental health services.

There have also been studies that have looked at the long-term cost-offsetting properties of such investments. Cohen (1998), for example, looked at "high-risk youth" in the United States and the *potential* economic advantages from "saving" each individual by estimating costs over the lifetime associated with crime, drug misuse and dropout from school. The estimated monetary value of "saving each high risk youth" was estimated to be between \$1.7 million and \$2.3 million. Another study by Bonin *et al.* (2011) looked at the effect of group parenting interventions for young people with conduct disorder using simulation modeling (see Box 18.1 for discussion of simulation modeling and other types of health economics study designs; and see Chapter 13). The study suggested that the parenting intervention resulted in long-term benefits to the public sector and to society by reducing the chance that conduct disorder persisted into adulthood. Long-term benefits of the program were greatest to the health and criminal justice sectors.

Cohen and Bonin's studies were based on hypothetical (simulated) valuations, whereas a second example—the High/Scope

Box 18.1 Examples of health economics study designs**Randomized controlled trial**

The randomized controlled trial (RCT) is the gold standard experimental study design in which study participants are randomly assigned to two or more groups. Economic evaluations can be attached to an existing RCT, or an RCT might be designed specifically to evaluate, for example, the cost-effectiveness of a treatment. Although the design has high internal validity, it may not produce results that are widely generalizable.

Quasi-experimental study design

Quasi-experimental studies cover a range of designs and investigate the effect of an intervention without using random allocation. They tend to

have lower internal validity compared to RCTs. When performing economic evaluation, it is important to be confident about causality and that important confounding factors are taken into consideration.

Simulation modeling

Simulation modeling may use already published results from previous studies to estimate the impact of an intervention or changes in policy for a range of hypothetical scenarios. It may incorporate epidemiological or cost data from other sources to model costs and outcomes of intervention and control groups.

Perry Preschool Study—was based on direct observations. Although not focused on children with mental health problems, this well-known intervention has been quite influential because of its finding of substantial savings in relation to crime, education and welfare payments, as well as higher taxes paid by those people who went through the preschool program (see, e.g., the summary by Schweinhart, 2004; Heckman *et al.*, 2010). However, these findings relate to a very small sample of individuals, and generalization from this study has been far from straightforward.

Exploring cost-effectiveness

Knowing the costs in childhood associated with mental health problems helps decision-makers to gauge the component and overall societal impact of these conditions. Knowing what economic consequences these problems lead to in adulthood helps those same decision-makers focus their minds on the need for better preventive or treatment interventions in early years or subsequently. But neither of these bodies of evidence can tell a decision-maker how to make better use of available resources. For this purpose it is necessary to examine both the costs and the outcomes of different uses of those resources. This is what economists would recognize as the examination of *cost-effectiveness*.

Consider what happens following the development or introduction of a new treatment (say a new medication intended for treating childhood depression). Decision-makers face two central questions when considering whether to use or recommend this new drug as part of the treatment range. The first is the clinical question: is the medication effective in alleviating depressive symptoms and generally improving child health? Or, when considering two or more different drugs, which of them has the better outcome? If the answer to the clinical question is that the new medication is no better or perhaps actually worse than existing treatment options, then there is usually no need to consider its use any further, nor probably to look at relative costs. But if the new medication looks clinically effective, the decision-maker will then want an answer to a second question: is it cost-effective?

That is, does the treatment achieve the improved child outcomes at a cost that is worth paying?

These two questions (Is the treatment effective? Is it worth it?) are at the heart of cost-effectiveness analysis (CEA). It is important to emphasize that CEA does what it says on the label: it looks at *both* costs and effectiveness (outcomes). Comparing the costs of one intervention with the costs of another, without any evidence on outcomes, might be interesting but does not constitute an economic evaluation because it does not provide enough evidence to assist service professionals, managers or others to make informed choices between alternative uses of their scarce resources. Similarly, calculating and in some way comparing the costs and outcomes of a single intervention could be revealing, but again is not especially helpful (and not an economic evaluation) unless comparison is made with equivalent data for another service (or with the “do nothing” option), for otherwise the decision-maker will have no benchmark against which to judge whether the observed costs and outcomes are attractive enough to justify action.

Note that the second question in a CEA asks whether improved outcomes are “worth” the extra cost. Deciding what is or is not “worth” the cost is far from straightforward and not without controversy, as we discuss below.

There are different variants of cost-effectiveness that can be applied to decision-making in health and related contexts. They share a common approach to the conceptualization, definition, and measurement of costs, but they adopt different approaches when considering and measuring the outcome side of the evaluation, primarily because they seek to answer slightly different questions. There is, however, some potential for terminological confusion. The term “cost-effectiveness” is used to describe a specific variant of economic evaluation as well as to refer generically to the group of all such evaluations. In this chapter we are using the term in its generic sense, unless specifically stated to the contrary.

Question and perspective

The choice of evaluative approach therefore depends on the question to be addressed. If the question is essentially clinical—what is the most appropriate treatment for a child with

particular needs in particular circumstances, and whether to opt for one therapeutic package or another—then information is needed on the comparative costs of the different therapies and the comparative outcomes measured in terms of symptom alleviation, improved functioning and so on. In these circumstances, a CEA (in the narrow sense of the term) would be appropriate and sufficient (see the section on “Effectiveness measurement”).

If, to take a broader stance, the question is whether to invest available health system resources to treat either childhood depression or asthma, then decision-makers again need to know the relative costs of the two alternatives, but they now need a measure of effectiveness that uses a common metric across the fields of depression and asthma. The most common measure so employed is “utility,” generated from health-related quality of life scales (see “Utility measurement” below). In these circumstances a cost-utility analysis (CUA) is needed (also see below).

To widen the perspective even further, if the question is whether to invest more money in the health system or more money in improving transport, launching a new environmental policy or bolstering a country’s defense forces, then the research question becomes one of asking what are the comparative costs and merits of the different investment options, where “merit” will now need to be measured in a common unit across all of these broad areas of public policy. The usual choice of broad measure is monetary, leading to cost-benefit analysis (see “Benefit measurement”).

The choice of question clearly influences the type of evaluation needed, but the choices are not mutually exclusive: a single study could support more than one type of analysis and address more than one policy or practice-related question. A body of evidence which is well located within the clinical domain will be exactly what the treating professional needs but may not be appropriate for a higher level decision-making body, such as a health ministry. The broader the research question, the more demanding are the data needs: brutally summarized, cost-benefit analyses are usually harder to do than cost-utility analyses, which in turn are usually more difficult than cost-effectiveness analyses.

Linked to the specification of the question to be addressed is the *perspective* to be adopted. Is the evaluative information needed to help resource allocation within a particular agency (such as a child and adolescent mental health service), or within a particular system (such as the health care system or education system), or within a particular sector (such as government), or within the whole society? The breadth of perspective will determine the breadth of both the measurement of costs and the choice of measures of effectiveness or outcomes.

Cost measurement

There are a number of ways to categorize the costs associated with mental health problems. There are *direct costs* associated with the treatment services and associated supports, some of them delivered by nonhealth agencies. There are also *indirect*

costs, which may fall to families, or may be measured in terms of lost productivity because of future disruptions to employment patterns for children once they have reached adulthood, or current disruptions to employment for parents. There may also be some unmeasured costs, perhaps reflecting the burden carried by family members, or societal concerns about anti-social behavior. In evaluations, the usual approach is to try to measure these elements as long-run marginal opportunity costs (Knapp, 1993). This helps to ensure that a long-term perspective on resource implications is employed, that only those effects on resources attributable to the program or service user are counted, and that costs are reckoned as opportunities forgone, not just money expended. How broadly the costs are measured will depend upon the perspective taken for the evaluation, which in turn depends upon the purpose of the study.

In carrying out evaluations in practice, the economist would be looking for data on service use patterns from one or more source. The data might come from organizational “billing” systems, recording the amounts that are transferred between a payer and a provider for services used by individual children or families. This is a common approach in US research, for example (although usually only spanning one system—such as healthcare—at a time). In care systems without such payment mechanisms, there might nevertheless be routine information systems that record service contacts and referrals, which might provide the necessary data for an evaluation. However, in many countries there are no billing data, and organizational information systems are too rudimentary or inaccurate to provide the basis for cost calculation. In these circumstances, the usual approach is to collect information on patterns of service use through interviews with family members or service professionals (for which there are a number of tools, including the Client Service Receipt Inventory (Beecham & Knapp, 2001).

To the service use levels generated by information systems or from interviews the researcher would then attach unit cost estimates for each service. It is not always necessary to calculate these unit costs anew. In England, for example, there is an excellent annual compendium of such unit costs which is very widely used in applied research (Curtis, 2012). Nonservice costs are harder to measure than service costs, partly because of the difficulty of identifying the impacts (e.g., on parental employment patterns, or on a child’s own future earning capacity) and partly because of the difficulty of then attaching a monetary value. (For further discussion of these issues see Johnston *et al.*, 1999; Brouwer *et al.*, 2001.)

Effectiveness measurement

Probably the most intuitive mode of economic evaluation is CEA: it measures costs as set out above, and measures outcomes using instruments, and scales familiar from clinical studies, because its focus is symptoms, behavior, functioning, peer-group integration, and so on. A CEA is employed to help decision-makers choose between alternative interventions available to or aimed at specific patient groups.

An analysis would look at a single outcome dimension—such as change in a behavioral measure, or symptom-free days or self-esteem—and would then compute and compare the ratio of the difference in costs between two treatments to the difference in (primary) outcome (the so-called incremental cost-effectiveness ratio). Certain areas of child mental health lack robust studies (see Box 18.2), however, there are good examples of cost-effectiveness analyses across many other areas. For example, an evaluation of a home-based social work intervention for children and adolescents who have deliberately poisoned themselves by Byford et al (Byford *et al.*, 1999) measured suicidal ideation, hopelessness and family functioning as the main outcomes, and health, education, social care, and voluntary sector services as the basis for cost measurement. Their randomized controlled trial, involving 162 children aged 16 years or under found no significant difference in the main outcomes for costs, although parental satisfaction with treatment was significantly greater in the group that received a new social work intervention compared to those who received routine care.

Another example of cost-effectiveness based on a randomized controlled trial comes from Domino et al (2009). The study looked at the relative cost-effectiveness of three treatments for major depression: (a) fluoxetine alone; (b) cognitive behavioral therapy alone, and (c) a combination of fluoxetine and cognitive behavioral therapy). Costs of service use of participants in this study were evaluated at 36 weeks follow-up in relation to the number of depression-free days and quality-adjusted life years. Although the combination treatment was the most costly, it was also found to be the most cost-effective treatment overall.

An obvious weakness with the strict cost-effectiveness methodology is the focus on a single outcome dimension (which is necessary to compute ratios) when children and adolescents with mental health problems often have multiple needs for support and when most clinicians would expect to achieve improvements in more than one area. For this reason,

cost-effectiveness ratios are sometimes computed for each of a *number* of outcome measures. This is sometimes called *cost-consequences analysis*. This approach has the advantage of breadth but poses a challenge if two or more ratios point to different interventions as the more cost-effective: in these circumstances, the decision-maker must weigh up the strength of evidence.

Making trade-offs

Many evaluations of new interventions find them to be both more effective (the outcome profiles are better than for old or current interventions) but simultaneously more expensive. For example, one study (Cunningham *et al.*, 1995) found that a group-training parenting program had better outcomes but slightly higher costs than an individual program. How is the trade-off to be made between the better outcomes and the higher expenditure necessary to achieve them?

The net benefit approach seeks to explicate the nature of the trade-off. It is most commonly seen today in the construction of *cost-effectiveness acceptability curves* (CEACs). These curves show the probability that a new intervention will be cost-effective for each of a number of prespecified or implicit valuations of an outcome improvement by the decision-maker. The advantage of the CEAC approach is that it makes transparent the trade-offs faced by decision-makers.

Two studies by Byford and colleagues illustrate this approach in the field of child and adolescent mental health. The first example examines the cost-effectiveness of treating adolescents with major depression using selective serotonin reuptake inhibitors (SSRI) and routine specialist care alone, or in conjunction with cognitive behavioral therapy (Byford *et al.*, 2007b). The latter intervention was both more costly and less effective: adding CBT to SSRI and usual treatment did not look economically attractive. The researchers plotted a CEAC as a way to address uncertainty in the data: this showed that, even at a value of £50,000 per one-point improvement in mental

Box 18.2 Cost and benefits of programs for learning disorders

Learning disorders represent one area for which there is little published evidence on the cost-effectiveness of programs. Some encouraging evidence using interventions data combined with various cohort data is available and described below; however, more robust study designs are still needed

Challen *et al.* identified indicators of learning difficulties from the 1970 British Cohort Survey (BCS70) and the Longitudinal Survey of Young People, and examined the association between the indicators and various social and economic outcomes later on (Challen *et al.*, 2008). Combining these data with intervention data from a phonological awareness intervention for kindergartners (Schneider *et al.*, 1997) allowed for estimates of potential cost-effectiveness of the program. The substantial effect size found in the evaluation (spelling improved by 0.57 and reading by 0.26 standard deviations) suggested that the intervention was potentially very cost-effective. This finding appears promising, but there are several caveats in that the evaluation of the intervention was too small

to look specifically at the effects for individuals with learning disorders and did not include a long term follow up.

Machin and McNally investigated the cost-effectiveness of a specific reading intervention called “the literacy hour” (Machin & McNally, 2008). The intervention was implemented in English primary schools and targeted young people aged 5–11 years. The program aimed to improve literacy through a teaching framework incorporating focused literacy instruction and effective classroom management. Evaluation of the program demonstrated significant impact on reading and on school achievement. Again the BCS70 data were combined with the intervention data to estimate the impact of the intervention (in terms of reading score improvement) on future earnings. As the cost of the intervention was quite low (£26 (US\$38) per pupil per year), even with very conservative estimates of the impact, the economic benefits were between £1375 and £3581 (US\$2019–US\$5258).

health (measured by the Health of the Nation Outcome Scale for Children and Adolescents), the probability that adding CBT to SSRI treatment would be seen as cost-effective was only low (only 0.25). When the researchers used QALYs to measure outcomes, the probability that CBT added to SSRI would be cost-effective was considerably lower (no higher than 0.04).

The second study by Byford and colleagues compares three treatment options for adolescents with anorexia: inpatient psychiatric services, specialist outpatient psychiatric services, and general outpatient services (Byford *et al.*, 2007a). The study showed that specialist outpatient treatment tended to cost less and be more effective as measured by the Morgan–Russell Average Outcome Scale (MRAOS) score, an indicator of severity of anorexia. The plotted CEAC showed that at two-year follow-up, if a decision-maker's willingness to pay for a unit increase in MRAOS score were zero, there was a 78% probability that the specialty outpatient services would be cost-effective. At higher levels of willingness to pay, the probability of being cost-effective actually decreased, but specialist outpatient services remained the most cost-effective of the three options.

Utility measurement

A mode of economic evaluation that seeks to reduce outcomes to a single dimension is CUA, which measures and then values the impact of an intervention in terms of improvements in preference-weighted, health-related quality of life. The value of the quality of life improvement is gauged in units of “utility,” usually expressed by a combined index of the mortality and quality of life effects of an intervention. The best known and most robust such index is the Quality Adjusted Life Year (QALY).

CUA are being used increasingly in health economics evaluations. They have a number of advantages, including using a unidimensional measure of impact, a generic measure which allows comparisons to be made across diagnostic or clinical groups (e.g., comparing psychiatry with oncology or cardiology), and a fully explicit methodology for weighting preferences and valuing health states. But these same features have sometimes been seen as disadvantages: the utility measure may be seen as too reductionist; the generic quality of life indicator may be insufficiently sensitive to the kinds of change expected in schizophrenia treatment; and a transparent approach to scale construction paradoxically opens the approach to criticism from those who question the values thereby obtained. In particular, there are worries that the generic utility-generating instruments, such as the EQ-5D (EuroQol Group, 1990), which is recommended by the National Institute for Health and Care Excellence (NICE), and the SF-6D (Brazier *et al.*, 2002) and HUI3 (Petrou *et al.*, 2010), are insufficiently sensitive to the kinds of symptoms and functioning change observed for people with mental health problems, and particularly for children and adolescents.

On the other hand, cost-utility analyses avoid the potential ambiguities with multi dimensional outcomes in cost-effectiveness studies. The transparency of approach should obviously also be welcomed. Such an approach to economic

evaluation produces an estimate of the cost per QALY-gain from one therapy or intervention and another. Estimates of this kind can then inform health care resource allocation decisions or priority setting, such as in the work of the NICE which has responsibility in England and Wales for providing national guidance on promoting good health and preventing and treating ill health. NICE has a well-developed process for assessing economic evidence (NICE, 2008) and cost-effectiveness values certainly influence guideline development (NICE, 2008; Cerri *et al.*, 2013).

There have been few published cost-utility analyses in the child and adolescent mental health area, the study by Byford *et al.* (2007a) summarized above being one of the few. Gilmore and Milne (2001) used the same evaluative approach to compare the costs and effects of methylphenidate and placebo for treating hyperactivity. Theirs was a modeling (simulation) exercise rather than a study that collected primary data. Another contribution to the literature on utility and cost measurement comes from Petrou *et al.* (2010). Although the study did not perform a full CUA, it did estimate the costs and utilities associated with a range of psychiatric disorders from participants of the EPICure cohort (Wood *et al.*, 2000). EPICure is a population-based longitudinal study of infants born in the UK and Ireland. Utilities were based on parental responses to the Health Utilities Index (Torrance *et al.*, 1995). Findings suggested a £2000 (US\$2937) annual cost difference between children with and without psychiatric disorder.

There is a quandary facing researchers and decision-makers in the UK today, and in some other countries that have chosen a strategic evidence-based approach to health technology appraisal. A generic outcome measure such as the QALY, when combined with cost estimates, can point to ways of achieving improved value for money when decisions need to be taken across a broad area (such as across a number of diagnostic areas), but if that QALY measure is not sensitive enough to reflect all relevant differences in effectiveness, then it might not be a sound enough basis for such an important task.

Benefit measurement

Cost-benefit analysis asks whether the benefits of a treatment or policy exceed the costs. This would allow decision-makers to consider the merits not only of allocating resources within health care, but also to consider whether it would be more appropriate to invest in other sectors such as housing, education or defense. In this form of evaluation all costs and outcomes (benefits) are valued in the same (monetary) units. If benefits exceed costs, the evaluation would provide support for the treatment, and vice versa. With two or more alternatives, the treatment with the greatest net benefit would be deemed the most efficient. Cost-benefit analyses are thus intrinsically attractive, but conducting them is especially problematic because of the difficulty of valuing outcomes in monetary terms.

Comparing costs incurred (e.g., on treatments) with costs saved (e.g., on future health services no longer needed) is not a

Box 18.3 Determining the quality of economic evaluations

1 Have all the relevant costs been taken into account? As we have seen, there are many and various inputs to a broadly defined mental health system—from health, social care, education, housing, social security and other agencies—plus economic consequences in terms of lost productivity, premature mortality and family impact. It might be necessary to measure all of these, depending on the policy or practice question that needs to be addressed and the perspective necessary for the evaluation.

2 Are all the dimensions of effectiveness taken into account? Good mental health care is obviously not just about tackling clinical symptoms, but about improving an individual's ability to function in ways that are valued by them (such as performing well at school and integrating with peers) and of course about promoting quality of life.

cost-benefit analysis but a *cost-offset* comparison. This confusion is unfortunately still quite common. A cost-benefit analysis must measure outcomes (in terms of improved health or improved quality of life) and then convert them to monetary values. Consequently, studies such as that by Jacobson *et al.* (1998) of an early intensive behavioral program for children with pervasive development disorder or autism, which compared the costs of the intervention with cost savings into adulthood, are certainly interesting but not as helpful as studies that compare the costs and the outcomes of interventions.

The problem is that attaching values to the outcomes of child and adolescent mental health interventions is inherently complicated. Methodological advances in health economics may offer a way to obtain direct valuations of health outcomes by patients, relatives or the general public. These techniques ask individuals to state the amount they would be prepared to pay (hypothetically) to achieve a given health state or health gain, or they observe actual behavior and impute the implicit values (Olsen & Smith, 2001). They are likely to be quite difficult to apply in mental health contexts. Another approach that is beginning to be used more and more often to value health interventions is “conjoint analysis”: individuals are asked to rank different real world scenarios, which may consist of several dimensions (including, for instance, health outcomes, quality of life, time inputs, discomfort, and stigma) and by including cost as one of these dimensions a monetary value can be elicited (provided that respondents can make the necessary trade-offs). While quite complex, the conjoint analysis approach has the advantage of not specifically asking individuals to put a monetary value on health states or health gain, which can make the technique easier to administer than traditional willingness-to-pay studies (Ryan, 1999). Bodies such as NICE provide useful recommendations for appropriate methods to be employed in economic evaluations. These resources may also be useful in judging the quality of economic analysis, which is an important consideration for any type of evaluation (see Box 18.3).

Conclusion

The starting point for an interest in the economics of child and adolescent mental health is clearly scarcity: it is the recognition

that there are not, and indeed there never will be, enough resources available to meet all mental health (or other) needs of all children and families. There is still a notion abroad in some parts of some health systems that incremental growth in budgets will gradually remove all need, but this is naively over-optimistic, indeed irrationally utopian. We cannot and we must not avoid facing up to the choices that have to be made in the face of scarcity. In making those choices we would want our decision-makers to be transparent about the criteria that they are employing. For instance, are they looking to maximize effectiveness in terms of symptom alleviation or aggregate quality of life, or to redistribute resources to poorer communities within society, or to ensure that access to skilled resources is equally available to every family?

Within this set of criteria, cost-effectiveness obviously has a role to play. As noted earlier, the cost-effectiveness criterion should probably be seen as secondary. If, for example, a therapeutic intervention has been shown to be effective in improving the well-being of children and families, and appears to be more effective than currently available therapies, then it would be natural to ask about the relative costs of the two options and to compare those costs with the outcome gains. Balancing outcome improvements with higher costs is, however, quite a challenge. A great many economic evaluations across the health spectrum today find that new therapies (whether pharmacological, psychological or organizational) offer better outcome profiles than currently prevalent interventions, but they do so at higher cost. The decision-maker, whether this is the individual care professional working with children and families, or their line manager and budget holder, or someone near the top of the health ministry, then faces a difficult trade-off: are the better outcomes from the new intervention worth the higher cost of introducing that intervention?

Heckman argues that we need a better understanding of the dynamics of the life course in order to identify the optimal time points for intervention (Heckman, 2012). A developmental approach which models early, intermediate and longer-term outcomes, and examines how interventions and consequences vary over time, would help those charged with the difficult tasks of allocating resources to consider the relative benefits of various approaches to prevention and treatment. In addition to considering life-course and timing, context is also important. Some cost-effective interventions could be prenatal, which could be

important for global mental health: investing in sustainable pre-natal interventions could make good sense in low and middle income countries (Panter-Brick & Leckman, 2013).

Requests for economic insights in the child and adolescent mental health field are of many kinds. In this chapter we have illustrated some of them, including requests to measure the overall cost impact of a particular disorder or diagnosis (so called cost-of-illness studies). Second, there are cost-offset studies that compare the amounts expended on interventions with the longer-term savings from introducing those interventions. Third, and the most powerful and useful, are cost-effectiveness studies (using the term generically also to include cost-benefit and cost-utility studies): these weigh up and compare costs and outcomes, and therefore give a more complete and rounded view as to the consequences of introducing different interventions.

There is a concern that most of the completed economic studies that can be found in the international literature today have been undertaken in North America, parts of Western Europe and Australia. Unfortunately, the results of economic evaluations often do not transfer well from one health or care system to another, and therefore not well between countries. This is primarily because of the differences in the structure of health systems, financing arrangements, incentive structures and relative price levels. There might also be differences in the appropriate choice of comparator: a new therapeutic approach might look attractive compared to current arrangements in one country but not in comparison to what is generally the norm elsewhere. It is infeasible and certainly unnecessary to carry out an evaluation every time a policy decision needs to be taken, but evidence-based decisions are generally thought to be better than evidence-free decisions. This could mean using the results from a study carried out in another country, or updating a previous study, or carrying out a modest adaptation to adjust for context.

The available economics evidence base in the child and adolescent mental health field is growing, but only slowly. It is disappointingly under-developed at present in high income countries and almost completely absent in low and middle income countries, but more is now being invested in the area, including a number of new studies that will—in time—offer valuable new insights into the resource consequences and cost-effectiveness properties of different interventions aimed at meeting the needs of children and families.

CHAPTER 19

Legal issues in the care and treatment of children with mental health problems

Brenda Hale¹ and Jane Fortin²

¹The Supreme Court, UK

²Sussex Law School, University of Sussex, Brighton, UK

The universality of human rights

The issues are universal: how are mental health professionals to navigate their way between the responsibilities of the parents, the autonomy of the child, and their professional duties toward their patient or client? In this chapter we shall illustrate the relevant concepts by reference to the law of England and Wales.¹ But it is likely that the legal principles will be very similar in those western countries whose legal systems are derived from the common law of England and Wales, including Canada, Australia, New Zealand, and most of the United States.

Moreover, the issues engage with the human rights of both parents and child. The right to liberty and security of person, the right not to be subjected to torture or inhuman or degrading treatment or punishment, the right to physical and psychological integrity, the right to respect for family life, and the right to a fair trial have been recognized since the United Nations Universal Declaration of Human Rights in 1948, since translated into the binding International Covenants on Civil and Political Rights and Economic, Social and Cultural Rights in 1966, and supplemented by UN Conventions catering for specific groups, of which the Convention on the Rights of the Child (CRC) 1989 and the Convention on the Rights of Persons with Disabilities (CRPD) 2006 are the most relevant. In addition, members of the Council of Europe must become parties to the European Convention on Human Rights (ECHR) 1950.

In common law countries, such international treaties are binding in international law once ratified, but do not generally become part of the ordinary law of the land unless the national Parliament so provides. Under the United Kingdom's Human Rights Act 1998 (HRA), the rights guaranteed by the ECHR

became rights enforceable in the UK law. The UK has not legislated to incorporate the whole of the CRC or the CRPD into its domestic law; but the European Court of Human Rights in Strasbourg interprets the ECHR rights in the light of other international human rights instruments; so the CRC is increasingly finding its way into both the Strasbourg and the UK courts' judgments on children's rights issues.² Under its influence there is further support for the general movement toward now giving young people greater rights concerning their own future while reducing the supervisory rights of their parents.³ Something similar may eventually be said of the CRPD.

Most western style democracies have written constitutions which also protect fundamental rights. The oldest is the Constitution of the United States of America, with its Bill of Rights of 1791 and later Amendments. This does not explicitly protect many of the rights recognized in the Universal Declaration and other modern instruments, but a great deal has been achieved through interpretation, in particular of the "due process" and "equal protection" clauses in the 14th Amendment. The modern Constitutions of the independent Commonwealth countries protect enumerated fundamental rights which are largely based on those in the ECHR. In between are the "old" Commonwealth countries, which (apart from Australia) have their own Bill or Charter of Rights, such as the Canadian Charter of Rights and Freedoms 1982. National laws dealing with mental health issues have therefore to be judged against these constitutional standards.

² E.g. *Neulinger and Shuruk v Switzerland* (2012) 54 EHRR 31; *R (Williamson and Others) v Secretary of State for Education* [2005] UKHL 15, [2005] 2 AC 246 [80].

³ *R (Axon) v Secretary of State for Health and another* [2006] EWHC 37 (Admin), [2006] 2 FLR 206, [115].

¹ Scotland and Northern Ireland are separate jurisdictions with their own laws.

The different roles of the mental health professional

Most commonly, of course, a mental health professional will encounter a child or young person as a patient. In the UK, health care is a universal service, free to all (apart from some “persons from abroad”) at the point of need, regardless of ability to pay. Unlike both the education and social care services, however, the NHS can rarely be obliged to offer treatment or care which it does not wish to offer. However, mental health professionals, like all other professionals, owe a duty of care to their own patients. If they negligently fail to diagnose or to treat, and the patient suffers harm as a result, they may be held liable in damages: for example, a child psychologist who fails to diagnose dyslexia⁴ or a child psychiatrist who negligently diagnoses child abuse.⁵ The duty is owed only to their child patient and not to the child’s parents. The courts here and elsewhere recognize that if professionals also owed a duty to the parents, they might hesitate to diagnose abuse and the child would go unprotected.⁶

If health professionals wish to provide treatment for a child with mental health problems and either the child or his family resist this, they have a range of options available. These include persuading an approved mental health professional (AMHP) to invoke the compulsory procedures under the Mental Health Act 1983, persuading the local children’s services authority to bring care proceedings under the Children Act 1989 (CA), or themselves applying to a family court for an order authorising the treatment. The choice between these will depend on whether it is the parents or the child who are seen as the principal obstacle and what it is ultimately sought to achieve—treatment for the child or a different family environment. These are discussed in the next two sections. Any court proceedings are likely to require expert evidence from mental health professionals, discussed in the concluding section.

Mental health professionals may also be involved in providing advice to other statutory agencies. Thus, for example, psychological reports are part of the formal process of assessing and providing the child with a “statement” of his special educational needs, which the education authorities are then under a legal duty to meet.⁷ Unlike the health and social care services, the education services can be ordered by a tribunal to provide an individual child with the education which the tribunal decides that he needs.⁸ Occasionally, psychiatric reports are required in the criminal justice system, on those rare occasions when a specialist

mental health disposal is made, such as a hospital or guardianship order under the Mental Health Act 1983, or a youth rehabilitation order with a mental health treatment requirement under the Criminal Justice and Immigration Act 2008.

Intervening against the parents

If health or social care professionals encounter opposition to what they believe to be in the best interests of an individual child, the first question is whether it is appropriate to take action against the parents or against the child. With older children, the obstacle may well be the child. With younger children, the obstacle is generally the authority of the parents, known in English law as “parental responsibility.” The mother automatically has parental responsibility, sharing it with the father if they are married to one another, or if an unmarried father has acquired it by agreement, court order, or since 1 December 2003 by registration on the child’s birth certificate (CA, ss 2(1), (2), and (4)). The great majority of unmarried fathers are now registered.

In western democratic legal systems it is parents and families, rather than the State, who have the primary right and the primary responsibility to bring up their children: to meet their claims for nurture, care, and upbringing and to decide for themselves how this will be done. It is the hallmark of a dictatorship to gain control of the children and distance them from the varied and subversive influences of their families (Hale, 2005: 5). Hence article 8 of the ECHR, drafted in 1950 in the twin shadows of the Nazi totalitarianism of the recent past and the Stalinist totalitarianism of the then present, guarantees to everyone, parents and children alike, the right to respect for their private and family life, their home and their correspondence. The CRC also requires States Parties to recognize that “parents or, as the case may be, legal guardians, have the primary responsibility for the upbringing and development of the child. The best interests of the child will be *their* basic concern” (article 18.1, emphasis added). States Parties must also recognize “the right of the child to the enjoyment of the highest attainable standard of health and to facilities for the treatment of illness and rehabilitation of health” (article 24.1) and “that a mentally or physically disabled child should enjoy a full and decent life, in conditions which ensure dignity, promote self-reliance and facilitate the child’s active participation in the community” (article 23.1).

The rights of parents are not absolute, and there are various ways of overcoming their neglect of or opposition to treatment. The CA provides in section 3(5) that a person who does not have parental responsibility for a child but has care of the child may “do what is reasonable in all the circumstances of the case for the purpose of safeguarding or promoting the child’s welfare.” This provision would clearly authorize emergency treatment to save a child’s life or prevent serious deterioration in the child’s health whatever the parents said. It would also authorize routine measures where the parents’ views were not known and could not be obtained within a reasonable time. But it would not

⁴ *Phelps v Hillingdon London Borough Council* [2001] 2 AC 619 (none has succeeded).

⁵ *Cf X and Others v Bedfordshire County Council* [1995] 2 AC 633.

⁶ *D v East Berkshire Community Health NHS Trust and Others* [2005] UKHL 23; *B and Others v Attorney General of New Zealand* [2003] UKPC 61; [2003] 4 All ER 803.

⁷ Education Act (EA) 1996, Part IV. But as from 1st Sept 2014, “statements” will be replaced by Education, Health and Care (EHC) plans; see Children and Families Act 2014, Part 3.

⁸ EA 1996, s 326.

be reasonable to proceed with major non urgent interventions without consulting the parents.

Historically, the only means of putting pressure on the parents to agree to treatment was the threat of prosecution for child neglect or abuse.⁹ Some legal systems are still reluctant to go beyond this threat to secure parental compliance, but this will not help the child unless it is effective. And it is least likely to be effective against inadequate parents who simply do not appreciate the risks.¹⁰

For one-off situations, where the child is being properly looked after in other respects, a hospital or health care professional can apply to a court for permission to override the parent's objections. In English law this can be done either by invoking the ancient *parens patriae* jurisdiction of the High Court or by a "specific issue" order (CA 1989, s 8) authorising the treatment: for example, a blood transfusion for the child of Jehovah's Witnesses. Where two or more people have parental responsibility, each of them may act alone and without the other in meeting it (CA, s 2(7)), so the consent of one parent will usually suffice. But where they disagree, the other parent can take steps to prohibit the treatment until the matter is resolved by the court, so in practice such disputes may have to be taken to court. The same procedures can also be invoked by a professional who wants to *prevent* treatment to which a parent had agreed: for example, the sterilization of an 11-year-old girl with Sotos' syndrome.¹¹

Many children with mental health problems or learning difficulties are likely to present more long-term and complex problems. The family environment and dynamics may be an important part of the child's difficulties. If so, it may be necessary to bring proceedings to remove the child from the harmful environment. Indeed, in some cases, it may be thought necessary to remove the child at or soon after birth, in order to prevent his suffering harm to his mental or psychological health in the future. Responsibility for undertaking care proceedings lies, not with the health authorities, but with the local children's services authorities, which have the statutory responsibility to protect children from harm (CA, s 47 and Sched 2). This is because the eventual outcome of most care proceedings is that the authority will have to take parental responsibility for the child. Care by a local authority may not be ideal, but at least the authority should have, or have access to, the full range of facilities needed to take care of the child, including the health and education services. Neither the health nor the education services are equipped to cater for everything which parents should provide for their children, nor can they find alternative homes for children who need them.

It is not enough that such intervention is in the child's best interests. While some legal systems have a list of specific grounds

for taking children into care, section 31(2) of the Children Act 1989 focusses on actual or likely harm to the child. First, it must be shown that the child is suffering or likely to suffer significant harm. "Harm" means ill-treatment or the impairment of health or development (see Chapters 29 and 30). "Health" means physical or mental health. "Development" means physical, intellectual, emotional, social or behavioral development. "Ill-treatment" includes sexual abuse and forms of ill-treatment which are not physical. Hence it is very likely that a child with mental health problems whose health or educational needs are not being met will be suffering or likely to suffer significant harm. But it is not the object of the Act to supply children with ideal parents to replace the less than ideal parents which we all are. It is not enough that the children might do better with different parents. As Hedley J said in *Re L (Care: Threshold Criteria)*,¹² which was a case about children of parents with quite serious learning difficulties, "... society must be able to tolerate very diverse standards of parenting, including the eccentric, the barely adequate, and the inconsistent. It follows too that children will inevitably have both very different experiences of parenting and very unequal consequences flowing from it." So one problem is to distinguish "significant harm" from the ordinary consequences of growing up with parents who are learning disabled, mentally ill, substance abusers, criminals or whatever.

"Likely" does not mean "probable," but simply "a real possibility, a possibility which cannot sensibly be ignored having regard to the nature and gravity of the feared harm in the particular case."¹³ So quite a low risk of really serious harm might justify preventive action, whereas if the feared harm is less serious, a greater risk may be required. Section 31(2) also requires that the harm, or likelihood of harm, is attributable to a lack of reasonable parental care, because the child's carers have not provided or will not provide it, and not because the services themselves are failing to deliver what the child needs.

Once the harm threshold is crossed, the court can decide what order will be best for the child. It may be better for the child to make no order at all; but unless there is someone else (such as another family member) who is willing and able to take parental responsibility for the child, the only other choices are a supervision order and a care order. A supervision order places the child under the local authority's supervision, but without affecting the parents' own parental responsibility. Conditions for medical or psychiatric examination and treatment of the child can be imposed, if there is medical evidence to support it (CA, s 35 and Sched 3, paras 4 and 5). But supervision is rarely thought sufficient to protect the child from significant harm. A care order gives the designated local authority parental responsibility for the child, which can limit the parents' exercise of their responsibility. The court has no power to impose conditions or to insist that the local authority discharge their parental responsibilities in a particular way. This puts the court

⁹ Children and Young Persons Act 1933, s 1(1). A parent is presumed to have neglected a child in a manner likely to cause unnecessary suffering or injury to health if he has failed to provide the child with adequate medical treatment: s 1(2)(a).

¹⁰ *R v Sheppard* [1981] AC 394.

¹¹ *Re D (A Minor)(Wardship: Sterilisation)* [1976] Fam 185.

¹² [2007] 1 FLR 2050, 2063.

¹³ *Re H (Minors) (Sexual Abuse: Standard of Proof)* [1996] AC 563, 585F.

in a quandary. How can it know whether the order will be in the best interests of the child unless it knows how the authority plan to look after him and has some confidence that the plan will be carried out? This can be a source of frustration both for courts and for health care professionals whose recommendations for treatment are not always adopted by the local authority (Thorpe & Clarke, 1998), but courts have neither the resources nor the expertise to act as substitute parents for children.

In most cases, the real choice is between planning to reunite the child with his family and planning to place him with a permanent alternative family. This raises an even greater dilemma. If the authorities intervene early, before a child suffers permanent harm, the more likely it is that he can be successfully placed for adoption with a new family. The later things are left, the more harm is done, and the more difficult it will be successfully to repair the damage. The dilemma is particularly acute with emotional neglect or abuse which may take many years to result in significant harm to the child, if indeed they ever do. But can such early intervention be justified in human rights terms?

Article 8(2) of the ECHR permits interference by a public authority with the right to respect for family life only if three conditions are fulfilled. First, the intervention must be “in accordance with the law”; this means that it must comply with a national law which is sufficiently clear and certain for people to be able to conduct themselves accordingly. Second, the interference must be for one of the legitimate aims laid down; in this case, for the protection of the “health or morals” or the “rights and freedoms” of the child. Third, and most important, the interference must be “necessary in a democratic society”; this means that the steps taken must be proportionate to the legitimate aim pursued and the reasons given must be relevant and sufficient. The Strasbourg court generally allows a wide “margin of appreciation” to the national authorities in deciding whether to take a child into public care.¹⁴ But the aim when doing so must generally be to reunite the family; so steps which cut children off from their families of birth will be scrutinized with much more care. Permanent removal requires exceptional justification in the interests of the child.

If the court considers that the local authority should take steps to make possible the reunification of parent and child and the local authority fails to do this, a parent might complain that the authority was acting in breach of either her own or the child’s convention rights. If the court considers that the child needs a permanent family elsewhere but the local authority fails to take timely steps to find one, the child might have a claim that his family life should not have been taken away from him without providing him with an alternative family.

Separate court authorisation is needed under the Adoption and Children Act 2002 if the child is to be placed for adoption without the parents’ consent (see Chapter 22). This can be done at the same time as a care order is made or later. Parental consent can only be dispensed with if the court is satisfied that

the welfare of the child requires this (s 52). This is a test of necessity, not desirability.¹⁵ Compulsory adoption is clearly the most drastic possible interference in the family life of a child, his parents, and their wider family and the UK is unusual in allowing this. But in *R and H v United Kingdom*,¹⁶ the Strasbourg court held that it was justifiable to free a child for adoption without parental consent when it was clear that the child could not go back to parents who had a long history of alcohol abuse. This was despite the expert evidence that the child needed to retain contact with her parents, so that every effort should be made to find adopters who would support that contact, and the proceedings should be adjourned to enable that to be done. But the Strasbourg court reiterated that “measures which deprive biological parents of the parental responsibilities and authorize adoption should only be applied in exceptional circumstances and can only be justified if they are motivated by overriding requirements pertaining to the child’s welfare” (para 81).

The particular dilemmas arising where it is feared that a parent’s mental health problems may cause psychological harm to a child in the future are well illustrated in the Supreme Court case of *Re B*.¹⁷ The mother had a history of sexual abuse in childhood and had begun a long and abusive relationship with her controlling and violent stepfather when she was still under 16. She also had a history of presenting herself to many different hospitals and doctors with a variety of symptoms, some of which had a physical explanation, but the history satisfied the diagnostic criteria for somatisation disorder. There were also indications of factitious illness disorder, though not of the so-called Munchausen syndrome by proxy. Eventually she succeeded in extricating herself from the relationship with her stepfather (leaving behind their daughter, then aged 10) and formed a relationship with the father of her new baby. When the baby was born, there was such a confusion of accusation and counter-accusation from the mother and her stepfather, in which the dreaded word “Munchausen’s” featured, that the child was removed on an interim care order shortly after birth. But the parents showed during regular contact that they were devoted to her and well able to cater for her immediate needs and she became strongly attached to them. The trial judge found that there was a risk that she would suffer psychological harm from her mother’s somatisation disorder, and quite extraordinary propensity for lying and deceptive behavior, and some risk of her being exposed to unnecessary medical examinations and treatment. The judge also found that the parents would not be able to cooperate with social services in a programme of monitoring and support to avoid these risks, so there was no alternative but to agree to the local authority’s plan for adoption.

Was this “significant harm” or was it just the ordinary risk that a child might pick up bad behaviors from her parents? Was the unquantified risk of the child doing so a sufficiently “real possibility” to justify compulsory preventive action? Above all, was

¹⁴ E.g. *KA v Finland* (2001) 2 FLR 696.

¹⁵ *S v L* [2012] UKSC 30, 2012 SLT 961.

¹⁶ [2011] 2 FLR 1236.

an unquantified risk of this sort of psychological or emotional harm at some time in the distant future sufficient to justify the most drastic step of all, the separation of the child from her parents at birth and placement in a closed adoption? The Supreme Court upheld the judge's decision, but one of the Justices dissented on the ground that this was not a proportionate response to the risk presented.

Intervening against the child

When health or social care professionals encounter opposition to what they believe to be in the best interests of an individual child, the source of the problem may be the child's own resistance. Traditionally the assumption was that the right to decide the medical treatment of a child rested with his parents. Today, this approach is being reassessed, particularly in relation to adolescents, many of whom have an intellectual development on a par with many adults. Although most countries have a relatively high age of legal majority (18 is the most common in countries in the EU), there has been a growing realization worldwide that long before this, many adolescents acquire a strong personal interest in taking responsibility for decisions affecting their future.

The child's right to consent to treatment

In England and Wales where the age of majority is 18, legislation enables 16 and 17 year-olds to consent to surgical, medical, or dental treatment themselves with no need to seek parental consent.¹⁸ But what of those under the age of 16?

In the late 1980s, the groundbreaking decision of the House of Lords in *Gillick v West Norfolk and Wisbech Area Health Authority (Gillick)*¹⁹ established that even a child under 16 who had sufficient understanding was able to give a valid consent to medical treatment and advice. It was a question of fact, to be decided on a case by case basis, whether the child had "sufficient understanding of what is involved to give a valid consent in law." If the child was competent to consent, the parents need not be involved. The notion of "Gillick-competence" (or the "mature minor" doctrine) became widely used in common law countries by doctors dealing with young patients.²⁰

Although doctors were provided with more specific guidance when providing contraceptive advice and treatment without involving parents,²¹ in a more general medical context the

"Gillick-competence" test has been criticized for its ambiguities (NSW, 2008: 4.10); for leaving doctors to assess competence, with the possibility of judges second-guessing them in the event of a parental challenge (Parkinson, 1986: 14); for ignoring the realities of every day medical practice (Cretney, 1985: 173); and for failing to provide doctors with clear guidelines (Brazier & Bridge, 1996: 91–92). In particular, it contains no guidance as to the extent to which an adjustment should be made for factors affecting adolescents' understanding, such as peer pressure, drug and substance abuse, family stress, emotional disturbance, risk taking, physical and mental illness—all matters which might radically influence their ability to attain *Gillick* competence (Fortin, 2009: 82–86).

Doctors may therefore be in some doubt over their precise legal standing regarding treatment without parental consent. In the UK, legal developments in relation to determining the capacity of adults with mental disorders or disabilities may prove useful. This topic was much explored through case law and by official bodies (e.g., Law Commission 1995), culminating in the test of capacity laid down in section 3 of the Mental Capacity Act 2005 (MCA). An adult is presumed to have capacity and is only unable to make a decision for himself if he is "unable (a) to understand the information relevant to the decision; (b) to retain that information; and (c) to use or weigh that information as part of the process of making the decision; or (d) to communicate his decision (whether by talking, using sign language or by any other means)." Although the Act only applies to adults, doctors may find that the same concepts are helpful when deciding whether a child is *Gillick*-competent.

It is not entirely clear how the concept of *Gillick* competence fits with the principles of human rights law. The CRC and the CRPD deliver a rather different message from the one sent out by *Gillick*. Article 12(1) of the CRC requires States to give all children who are capable of forming their own views, the right to express these freely in all matters affecting them and the right to have their views given "due weight in accordance with the age and maturity of the child." Article 7(3) of the CRPD requires children with disabilities to be given that right on an equal basis with other children, and to be provided with disability and age appropriate assistance to realize that right. This gives every child, not merely a *Gillick*-competent child, the right to *participate* in decision-making about himself, and (in the CRPD) to be helped to be able to do so. But, unlike *Gillick*, this right to be consulted is not about autonomy: it does not give children the right to decide matters for themselves.

Turning to the ECHR, one might assume that article 8 of the ECHR reinforces the concept of *Gillick* competence and autonomy. In case law concerning adults, the Strasbourg court has emphasized that it protects the right to respect for physical and psychological integrity, and includes the right to

¹⁸ Family Law Reform Act 1969, section 8 (2). See also Age of Legal Capacity (Scotland) Act 1991, section 2(4).

¹⁹ [1986] AC 112.

²⁰ E.g. *Secretary, Department of Health and Community Services v JWB (Marion's case)* (1992) 175 CLR 218 (Australia); *JSC v Wren* (1986), 76 AR 115 (CA) (Canada).

²¹ Lord Fraser in *Gillick* stated that the doctor should be satisfied: (1) that the girl (although under 16) will understand his advice; (2) that he cannot persuade her to inform her parents or allow him to inform the parents that she is seeking contraceptive advice; (3) that she is very likely to begin or to continue having sexual intercourse with or without contraceptive treatment;

(4) that unless she receives contraceptive advice or treatment her physical or mental health or both are likely to suffer; and (5) that her best interests require him to give her contraceptive advice, treatment or both without the parental consent. And see Department of Health (2004).

self-determination or the “notion of autonomy”²²; it protects against compulsory medical intervention even if that intervention is of minor importance.²³ In theory these rights are available to everyone, irrespective of age and certainly irrespective of opposition from third parties, such as parents. But in a rare (and controversial) early decision about the psychiatric care of a child, the European court adopted a conservative approach to the notion of children having rights against their parents.²⁴ Nevertheless, the High Court has since held that the concept of *Gillick* competence is unaffected by a mother’s (article 8) right to bring up her daughters free from state interference—that her rights are not so extensive that they override her daughters’ own (article 8) right to medical privacy.²⁵

Overriding the child’s refusal to consent to treatment

But where does this leave the “*Gillick*-competent” teenager who wishes to refuse consent to what is proposed? *Gillick* appeared to give mature minors the right to decide for themselves what medical treatment they should *or should not* receive. How then should a doctor respond to a desperately ill adolescent patient who rejects even lifesaving treatment (Ferguson, 2004; NSW, 2008; Irish Law Reform Commission, 2011)? Crucially, did Lord Scarman’s words that the “parental right yields to the child’s right to make his own decisions when he reaches a sufficient understanding and intelligence to be capable of making up his own mind on the matter requiring decision” (*Gillick*, p. 186) preserve the right of the parents to give an alternative consent (Fortin, 2011: 202–208; Herring *et al.* 2012: 62–68)?

While most doctors sympathize with the need to adopt more liberal attitudes toward adolescents’ own powers of consent, they are also aware that some adolescents are particularly ill-equipped to reach decisions which affect their long-term well-being. An adolescent’s capacity to make wise health care decisions may be greatly hampered by emotional and social immaturity, risk-taking behavior and a concern only for the short-term consequences of decisions (NSW, 2008: 2.29–2.34).

Given these factors, it is arguable that young people’s capacity to make health care decisions should require not only the competence to understand information relating to the proposed health care and to consider multiple options, but also to choose voluntarily, free from outside influence, and to appreciate the nature of the decision—in terms of its gravity, immediacy, and the permanence of the choice. “Decision-making competence should be linked not just with developing cognition, but also to life experience and experience in making decisions” (NSW, 2008: 2.31). Arguably, the MCA definition (see above), with its

emphasis on the ability to use the information understood in order to arrive at a free choice, would meet this concern.

On the other hand, in developmental terms, an adolescent’s brain is more like that of an adult than that of a young child—and an adolescent patient may be just as intelligent as many adult patients. The fact that serious risks or consequences may result from an *adult*’s refusal of medical treatment does not undermine his or her right to self-determination—a choice not to allow treatment must be respected, whether or not the professionals agree with the patient’s decision.²⁶ Why should an adolescent patient be treated any differently, particularly now that society perceives young people as individuals with rights and points of view of their own?

In two English cases decided in the 1990s, doctors faced with adolescents refusing lifesaving treatment made their patients wards of court in order to side step that refusal. Both applications involved adolescents with serious psychological problems.²⁷ The Court of Appeal held that under its inherent jurisdiction it could override a young patient’s wishes and authorize lifesaving treatment in his or her best interests. Although not necessary for the decision, it went further and said that *anyone* with parental responsibility for a minor patient could authorize doctors to carry out much needed treatment despite the patient’s own clear opposition. This authority could be granted whatever the patient’s age (over or under the age of 16) and whether or not he or she was *Gillick* competent. Such a judicial response is not surprising and has been followed in later cases. Given the courts’ protective responsibility for all minors, they may find it impossible to conclude that it is in the child’s best interests to be allowed to die.²⁸ The Court of Appeal was also concerned to provide doctors with a legal “flak jacket” protecting them against litigation where the minor has refused treatment.²⁹

Although convenient for doctors, this principle makes substantial inroads into the principle of adolescent responsibility established in *Gillick* (Douglas, 1992). It has also produced a situation that appears illogical and confusing. The law allows a *Gillick* competent adolescent to consent to medical treatment, which the parents have no right to veto. But it allows those same parents to override that same adolescent’s refusal to accept such treatment. Most of all, it is one thing to allow a *court* to override the child’s decision after a fair hearing in which all sides of the argument have been properly ventilated. It is another thing to allow a parent—or worse still a local authority with parental

responsibility—the right to force unwanted treatment on a competent child.

When considering this issue, the New South Wales law reformers considered that the parental right of veto should be jettisoned but that the courts' right to override their refusal should be retained where a young person's decision is considered to damage his or her best interests (NSW, 2008: paras 5.44–5.45). In their view it was important for the courts to retain this power; a paternalistic approach was justified because “young people, even as they reach the intellectual or cognitive capacities of adults, still as a group tend to lack a certain level of maturity and world experience because of their youth” (para 2.64). Furthermore, it was important for the courts to have the power to save adolescents from making medical decisions which they might later regret and which might hinder their longer life chances (para 2.73).

Cases of this kind may be complicated by the existence of a religious element. An adolescent growing up in a deeply religious home with parents opposed to certain kinds of medical treatment may have a limited opportunity for independent thought (Brazier & Bridge, 1996: 104); but overriding firmly held religious convictions will undoubtedly reinforce distress over enforced treatment. Courts here and abroad have shown little appetite for allowing the wishes of adolescents with strong religious views to dictate a fatal outcome.³⁰ English courts have sometimes found a way round this dilemma by adopting a stringent approach to the assessment of young patients' competence. Young Jehovah's Witnesses have been held to lack competence because they do not understand the manner of their impending death, together with the pain and distress accompanying it.³¹ Critics point out that although few adults can comprehend the process of dying, the pain they would suffer, the fear they would undergo and relatives' distress in watching them die, neither doctors nor the courts are entitled to overrule their refusal to undergo treatment for similar reasons (McCafferty, 1999).

This issue has not so far reached the UK Supreme Court. But in *AC v Manitoba (Director of Child and Family Services)*,³² the Supreme Court of Canada dealt with a challenge from AC, a 14-year-old Jehovah's Witness, forced to undergo blood transfusion treatment for a life-threatening condition. Its survey of international approaches to this problem, including that of the English Court of Appeal, showed that other jurisdictions were finding it equally difficult to allow adolescents to reject lifesaving treatment: “... courts ... have generally not seen the ‘mature minor’ doctrine as dictating guaranteed outcomes, particularly where the consequences for the young person are catastrophic” (para 69). The majority considered that the provincial legislation giving the courts a discretionary power to authorize medical treatment for adolescents under the age of 16, even against their wishes, did not unduly infringe AC's constitutional right to freedom from forced medical treatment. The state had a legitimate

concern to protect younger adolescents as a vulnerable group from making decisions before attaining capacity for truly mature and independent thought.

While this judicial approach is comprehensible, it is also controversial.³³ Some have argued that enforced survival to adulthood might not be in every child's best interests (Lewis, 2001: 159; Harmon, 2010: 95). There is also a concern that the courts sometimes find themselves on a slope too slippery to resist and do not restrict their interventions to circumstances where paternalism can be justified on lifesaving grounds. While it may be morally justifiable to override the wishes of a competent adolescent patient to prevent “death or severe permanent injury,” it is questionable where failure to treat will not produce such dire consequences—especially in mental health settings involving compulsory detention.³⁴ Furthermore, granting such authority may entail the use of physical force. As Gostin says, “Nothing degrades a human being more than to have intrusive treatment thrust on him despite his full understanding of its nature and purpose and his clear will to say ‘no’” (Gostin, 1992: 76).

Does human rights law hold the key to this problem? It provides child patients, like adults, with a right to freedom from arbitrary deprivation of liberty,³⁵ an absolute right to protection from inhuman and degrading treatment, and a qualified right to respect for their physical and psychological integrity.³⁶ On the other hand, like adults, they also have a right to life, which in certain circumstances includes the right of a vulnerable patient or prisoner to be prevented from harming himself.³⁷ Perhaps Strasbourg would regard an adolescent refusing lifesaving treatment in the same light. Furthermore, it takes the view that, in principle, treatment which is a “medical necessity” infringes neither article 3 nor article 8.³⁸ But that is in the context of detained psychiatric patients. It remains to be seen what view both the UK and the Strasbourg courts would take of a human rights challenge to the power of either the parents or the courts to impose treatment on a competent child who refuses it. Strasbourg's decision in *Storck v Germany*,³⁹ holding that an 18 year old's right to liberty was infringed when she was detained in a psychiatric hospital on her father's authority suggests that they might be willing to reconsider their early and controversial stand favoring parents' rights against children's rights in the context of medical decision making.⁴⁰ It has been suggested that *Storck* sent out

“a clear message indicating a different approach to the personal autonomy of young people.”⁴¹

Using mental health law

Sometimes children, more commonly adolescents, require specialized treatment for mental health problems and, rarely, their doctors need compulsory powers to ensure that this occurs. The Mental Health Act 1983 (MHA) applies to all patients requiring treatment for mental disorder, irrespective of their age (for a full account, see Hale, 2010). Where hospital treatment is needed, most patients are admitted informally under section 131(1), thereby avoiding the compulsory procedures.

In the past, the informal admission of mentally ill or behaviorally disturbed young people might be far from voluntary. Doctors were frequently reluctant to use the MHA to enforce their young patients’ detention and treatment (BMA, 2001: 140), the most common objection being the perceived stigma for the child, when adult, attached to the use of compulsory powers. It was tempting, therefore, for doctors to utilize the 1990s case law discussed above, and thereby rely on parental authority to admit patients under 18 informally, even against their will, with none of the safeguards available for those compulsorily detained under the MHA. Alternatively doctors could ask the court to authorize admission.

The Mental Health Amendment Act 2007 introduced important new legal safeguards for older adolescents regarding their informal admission. This responded to critics arguing that children, whether competent or not, had liberty interests which should be protected against the well-meaning but possibly arbitrary decisions of their parents. Parents should not be able to “volunteer” their children for informal admission for psychiatric treatment without some additional safeguard, such as an automatic tribunal review (Gostin, 1975). Now, where a patient aged 16 or 17 has capacity to consent to informal admission to hospital for treatment for mental disorder, and does consent, the arrangements may be made on his or her authority, even though there are one or more persons who have parental responsibility for him (s 131 (2), (3)); and where such a patient does *not* consent, the arrangements may *not* be made, even though a person with parental responsibility does consent (s 131(2), (4)). So doctors can no longer bypass the refusal of a patient aged 16 or 17 who has capacity, by obtaining parental consent. They will have to choose between using compulsion under the MHA and going to court (Code of Practice, 2008: 36.27–36.33). The young patient’s capacity to consent should be judged, not by the broad test of *Gillick* competence, but by the more explicit criteria of the Mental Capacity Act 2005 (s 3; discussed above).

The MHA does not deal with the position where a child under the age of 16 also has that capacity. Presumably, therefore, the *Gillick* principle will apply where the child does consent

to admission. Where a competent child refuses to agree to admission, the Code of Practice advises that “the trend in recent cases is to reflect greater autonomy for competent under 18s, so it may be unwise to rely on the consent of a person with parental responsibility” (para 36.43). If so, as with the older age group, the professionals will have to choose between the compulsory procedures in the MHA or asking the court to authorize admission and treatment.

Where a child of any age is not competent, or expresses no view about his admission, it will generally be possible to rely on parental consent to his or her informal admission. The Code points out that the child may have the intellectual capacity to make a decision but in fact be so overwhelmed by the situation that he is unable to do so (paras 36.28 and 36.37). But before doctors turn to parents for legal authority, they should perhaps reflect on the wisdom of doing so, given how difficult parents will find it to be objective over their children’s mental health needs.

Admission and treatment are different matters legally. Informal patients may not be treated without valid consent or some other lawful justification, so the same legal principles as those discussed earlier will apply. In other words, for those aged between 16 and 17, their competence to consent to treatment will be assessed by the criteria set out by the MCA; competence to consent for those under 16 is assessed by the *Gillick* competence criterion.

Where informal admission or treatment is not possible, the same compulsory powers to admit for up to 28 days assessment (under section 2), or for up to 72 hours in an emergency (under section 4), or longer term for treatment (under section 3) are available for patients of any age. Although, as noted below, these procedures have features designed to protect the human rights of mental patients, they must obviously be effective to overcome the objections of the patient and, when relevant, the objections of a parent. A patient’s nearest relative (usually his parent, if the patient is a minor) has no right to prevent an approved mental health professional (AMHP) making an application for short-term admission under section 2 or section 4, although “before or within a reasonable time,” the AMHP must “take such steps as are practicable” to inform that person that the application is to be or has been made (s 11(3)). An AMHP cannot make an application for long-term admission for treatment under section 3 without first consulting the nearest relative, unless this is not reasonably practicable or would involve unreasonable delay (s 11(4)(b)); active consent of the nearest relative is not required, but the application cannot be made if he objects (s 11(4)(a)). But there is a process for applying to a court to replace a nearest relative who unreasonably objects to the admission or is otherwise unsuitable (s 29).

The Act recognizes that removing a person’s liberty in order to compel him to accept treatment is a drastic step and so the criteria, the procedures and the consequences are clearly defined. Most forms of treatment for mental disorder may be given without the patient’s consent (s 63); this includes

⁴¹ *Austin v Metropolitan Police Commissioner* [2009] UKHL 5, [2009] 1 AC 564, [45], Lord Walker.

force-feeding for anorexia nervosa.⁴² There are special safeguards for neurosurgery, long-term medication and ECT (ss 57, 58, 58A). Neurosurgery cannot be performed on any patient, whether or not he is detained, unless the patient is capable of consenting to it, does so consent and an independent multi-disciplinary team certify that it should be given (s 57). Patients under 18, whether or not they are detained, cannot be given ECT without the benefit of an independent second opinion (ss 56(5) and 58A). Patients also have the right to apply to a tribunal for their discharge.⁴³

It appears that attitudes to the use of the MHA for minors are gradually changing and that, particularly when treating eating disorders in older adolescents, doctors are now more prepared to envisage its use. As discussed above, the law now acknowledges the autonomy rights of mentally ill or behaviorally disturbed 16- and 17-year-olds so far as informal admission is concerned. But in other respects, because of the law's complexity and uncertainty, young patients' rights can be overlooked. There is a difficult balance to be struck between the protection given by legal formalities and the stigma they are sometimes thought to bring. But doctors specializing in child and adolescent psychiatry are more used to negotiating these dilemmas than any lawyer could ever be.

Expert witnesses

Compulsory procedures under the MHA require the prescribed medical recommendations explaining that the statutory criteria are made out (MHA, s 12). The patient's responsible clinician will usually be called up to give evidence if the detention is challenged in a tribunal and the patient may have the benefit of an independent psychiatric report. Mental health professionals are also frequently called up to give expert evidence in court proceedings about a child's future, assessing either the parents' mental health or parenting capacities, or the child's mental health and development, or both. Experts differ from other witnesses in that they are permitted to give evidence, not only as to the facts, but also as to their opinions. In children's proceedings they are allowed to base those opinions on hearsay.⁴⁴ But they should be willing to acknowledge that medical records are not always perfectly accurate or complete and may from time to time repeat or rely on unverified hearsay.

Expert witnesses fall into two broad categories, although the distinction between them is not always clear cut. Professionals who are already working with the child or his family may be asked to report on the history, diagnosis and treatment to date, together with their assessment and recommendations

for the future. Independent experts may be commissioned to investigate, sometimes only on paper and sometimes also by seeing the parties, and to make a report and recommendations to the court.⁴⁵ Such reports may be commissioned by any of the parties to the case, but the court is in charge of whether and how many experts may be instructed and in which disciplines.⁴⁶ One original aim is to prevent the child being subjected to multiple examinations and assessments (Butler-Sloss, 1988). Another is to prevent the proceedings becoming unnecessarily prolonged and expensive.

The court has power to require an assessment of the child but not the treatment of the parents.⁴⁷ This does not always reflect the realities of psychiatric practice. In some of the most complex and difficult cases, it is not possible to separate the assessment of the child from the assessment of the parents.⁴⁸ What requires assessment is the relationship between them all and the capacities of the parents to meet the needs of the child. What begins as assessment may move into assessment with therapy and move again into therapy with continuing assessment. It has been forcefully argued that doctors are assessing their patients all the time (Kennedy, 2001). Our nice legal distinctions mean nothing to them. This would not matter were it not for the problems of funding the very specialist resources which some of these deeply damaged families require. The court can only require the parties to pay for an assessment which is necessary to enable the court to perform its own function of deciding what order to make.

There is another problem in child protection proceedings (Norgrove, 2011: para 33): the quality of evidence presented by local authorities to the courts is "not consistently good"; "this fuels distrust and lack of confidence in local authority social work"; and the reluctance of courts to rely on local authority social workers rather than other experts "encourages authorities to think there is little point in carrying out their own expert assessment before a case begins." Hence the courts became disinclined to rely on evidence provided by local authorities and turned to independent experts instead (Pearce *et al.*, 2011).

The court may require the parties to agree on a single, jointly instructed expert. Even then, some cases require expertise in more than one discipline.⁴⁹ And while the battle between separately instructed experts can be unedifying, especially if one or other is seen as a "hired gun" for the instructing party, a single joint expert brings problems for a party who wishes to challenge his conclusions. Parents or children's guardians who have serious concerns about the accuracy or rigor of an expert's report face formidable difficulties if they try to challenge it without expert evidence of their own. It is not easy to reconcile the need of the child to be spared multiple and intrusive investigations, and to

have the issues about his future resolved without delay, with the right (guaranteed by article 6 of the ECHR as well as the common law) of both the child and his family to a fair trial of the issues. Added to this was the reluctance of courts to make a final order which would hand over complete responsibility to the local authority (Norgrove, 2011).

The result was that by 2011 the more complicated care cases were taking more than a year to resolve. Experts were used in around 92% of care order applications, with a staggering average of 3.9 reports per case (Cassidy & Davey, 2011). The bulk of these were from adult or child psychiatrists or psychologists (Chief Medical Officer, 2006: para 2.13). They were prepared on a fee-paid basis, funded by the Legal Services Commission at levels which deterred the more experienced and better qualified practitioners from taking it on, leaving the task to more junior or retired practitioners. Hence there was also criticism of the quality of much of the psychological evidence given in care cases (Ireland, 2012).

In 2006, the Chief Medical Officer proposed that the NHS should recognize that its duty under the Children Act 2004 to safeguard and promote the welfare of children should extend beyond caring for the sick and injured and into providing expert medical evidence for the family courts as a public service. NHS Trusts should set up specialty and multidisciplinary teams for that purpose. But that proposal has still not been taken up, except in pilot projects. Instead, expert evidence can now only be commissioned where it is *necessary* to resolve the case and the information is not already available from other sources.⁵⁰ The court, rather than the parties, should decide what questions the expert should address. The expert's overriding duty is to the court and takes precedence over any duty to the party who instructs him. An expert witness enjoys immunity from suit in respect of his evidence but not the investigations leading up to it⁵¹; but this does not protect him from professional discipline if, for example, he goes beyond the limits of his expertise⁵²; and he may be held liable in negligence to the party who instructs him.⁵³ In family proceedings, a lack of contradiction or opposition will place a heightened duty of independent professionalism on the expert witness and of vigilance on the court.

Conclusion

Children with mental health problems present more legal issues than do adults: there is the parents' responsibility for and authority over the child, as well as the more problematic question of the child's own autonomy. Mental health professionals are now much more aware of such questions than once they

were. Fortunately, most of the time they are able to treat their patients without disputes or challenge. It is always better to try and reach agreement rather than to resort to the blunt instrument of legal proceedings which may polarize positions and make future cooperation for the sake of the patient more difficult.

CHAPTER 20

Children's testimony: a scientific framework for evaluating the reliability of children's statements

Maggie Bruck¹ and Stephen J. Ceci²

¹School of Medicine, Johns Hopkins University, MD, USA

²Department of Human Development, Cornell University, NY, USA

In the past 30 years, there has been an outpouring of research on the accuracy and distortion of children's autobiographical memory. The major issues concern how much children can remember of their near and far past, and the degree to which such factors as age of the child, salience of the event, delay, stress level, and an array of psychological factors (e.g., intelligence, personality) influence their recall. A second major issue concerns the degree to which a variety of external factors, mainly viewed in the interviewing process (e.g., leading questions, false suggestions, rewards), can distort children's testimony to the point that children will falsely report unexperienced events. In this chapter we focus on the latter issue—one that has been termed “children's suggestibility.”

In the 1990s and into the first decade of the 21st century, much of the research focused on preschool-aged children, and was framed to address issues concerned with sexual abuse. This was primarily due to significant numbers of criminal cases in the 1980s and early 1990s in which young children claimed that their parents or other adults, often in daycare settings, had sexually abused them. The claims were often fantastic and bizarre, involving reports of ritualistic abuse, animal sacrifice, pornography, witchcraft, multiple perpetrators, and multiple victims (Nathan & Snedeker, 1995; Bottoms & Davis, 1997; De Young, 2004). When these types of cases first came to trial in the 1980s, the major issue before the jury was whether to believe the children. Prosecutors argued that children do not lie about sexual abuse, that their reports were authentic, and that their bizarre and chilling accounts of events, which were beyond the realm of most preschoolers' knowledge and experience, confirmed the fact that the children had actually participated in them, otherwise how could they graphically describe events beyond the ken of the typical child. The defense in these cases argued that the children's reports were the product of repeated suggestive interviews by parents, law enforcement officials, social

workers, and therapists. Although the defense identified an array of potentially “suggestive” interview techniques that were associated with the evolution of children's allegations, at the time there was no direct scientific evidence to support the view that such techniques lead children to make incorrect disclosures of a sexual nature. Consequently, in many of these cases the defendants were found guilty and sentenced to long prison terms (Ceci & Bruck, 1995; Nathan & Snedeker, 1995). As a result of such cases, social scientists pioneered the path to providing a social-psychological explanation for the conditions that promulgated such accusations. In doing so, we acquired valuable knowledge about the normal development of the preschool child—a field that was relatively underresearched at that time. As a consequence of new research, many, but not all, of the alleged perpetrators successfully appealed and were pardoned.

Although the daycare cases have all but disappeared from the forensic arena, research on children's autobiographical memory has continued to flourish and to be used in the forensic arena where there is concern about the accuracy of the testimony of children who were alleged victims, participants, or witnesses to a variety of events (e.g., sexual abuse, physical abuse, eyewitness to a crime). This area of research also is important for professionals and caretakers who question children or try to get them to talk about less traumatic issues. In this chapter we highlight the most prominent scientific findings in this field and demonstrate how these findings provide an objective framework for evaluating the reliability of young children's false claims, focusing on allegations of sexual abuse that arose in the course of a divorce/custody case.

Before proceeding, it is important to emphasize that most cases that involve child allegations of sexual abuse do not raise issues about suggestion and about false reports (see Chapter 30). Many children readily disclose their abuse either spontaneously or when asked in a neutral setting (see review by London

et al., 2008). There are also many children who do not disclose abuse because they are afraid, ashamed, and embarrassed; these numbers are unknown. Nonetheless, the smaller proportion of children who make false allegations is an important area of study because the results indicate a number of measures that can be taken by experts and clinicians to avoid such outcomes in a variety of cases going beyond sex abuse allegations, and also because these studies are crucial for our understanding of the development of the child's autobiographical memory system.

We begin this chapter by defining a variety of concepts and experimental paradigms that characterize this scientific area.

Defining suggestibility. One's recall of past experiences is rarely error-free. Errors can occur for a variety of reasons such as forgetting, lapses of attention in experiencing the event or in recalling its details, blocking of the memory by other experiences, or blending of two or more different memories (e.g., see Schacter, 2001). Recall of one's past can also be distorted by one's beliefs or expectations about what should have happened. And finally, recall can be distorted by suggestions—interactions with others that result in incorporation of their beliefs and statements into one's own report.

Suggestions become incorporated into reports for a variety of social and cognitive reasons. Cognitive theories suggest that the original memory trace can be damaged, replaced or overshadowed by suggestions—both internally generated such as ruminations and scripted expectancies, and externally generated such as interviewer-provided misleading information (Brainerd & Reyna, 2005; Otgaar *et al.*, 2012a, 2012b). In contrast, social theories posit that false reports reflect compliance with the interviewer or the group (Gudjonsson, 1989; Billings *et al.*, 2007). Compliance reflects trust in the knowledge of the interviewer (e.g., Lampinen & Smith, 1995; Waterman *et al.*, 2004; Mills, 2013), or at the other end of the continuum wanting to go along with the peer group (Pynoos & Nader, 1989). Compliance can occur when there is no memory or a gap in the memory and the suggestion is used to fill that gap. Both social and cognitive mechanisms may jointly lead to suggestibility effects: a child may initially acquiesce due to social factors (e.g., to please their interviewer) but over time the child comes to falsely believe that the suggestion actually occurred (e.g., Bruck & Ceci, 1999; Stolzenberg & Pezdek, 2013).

Reliability, competence, credibility. These three terms are often used interchangeably but inaccurately in the context of the legal arena. In the legal context, reliability refers to the "trustworthiness" of the evidence, not to the honesty or credibility of a witness. Statements or reports can be unreliable due to normal processes of forgetting, of distortion, and of reconstruction. Statements can also be rendered unreliable if they are elicited in certain suggestive contexts. Thus, the existing literature on reliability focuses on factors that enhance or degrade the quality of witness reports. Although an assessment of the credibility (believability) of the witness and of the guilt of the alleged perpetrator are issues within the province of the jury, not the expert witness, the provision of information on the reliability

of the evidence is crucial to allow jurors or judges to draw conclusions about the credibility of children's allegations and ultimately about the guilt of the defendant. For several reasons, the scientific literature on reliability is rarely used to evaluate the "competence" of a witness. There are several reasons for this. First, there appears to be little, if any, relationship between the accuracy of children's recall and their performance on competence-type interviews (e.g., knowing the difference between a truth and a lie) that are often used in the courtroom (e.g., London & Nunez, 2002; Talwar *et al.*, 2004). Second, because the competence standard is quite undemanding (witnesses are deemed competent if they are sufficiently intelligent to observe, recollect, and recount an event, and have a moral sense of obligation to speak the truth), most witnesses are deemed competent by the court.

Experimental measures of suggestibility. There are two basic paradigms that have been used to examine the direct influence of various types of suggestions on the accuracy of reports. In the first paradigm, children are exposed to an event or activity about which the researcher has full knowledge of all the details, such as a staged robbery. After the event, children are asked to recall these experiences through the use of techniques that falsely suggest details that were not present during the event, or through neutral interviewing techniques that do not involve suggestion. Subsequently, children are asked to recall the original event. A comparison of the errors made in the suggestive and neutral conditions allows a determination of how much suggestions taint the child's reports. In the second major paradigm, children are given suggestions about whole events that (according to parent reports) their child had never experienced, such as going on a hot air balloon ride or having their finger caught in a mousetrap. The degree to which children assent to and provide details about nonexperienced events are measures of their suggestibility.

Outline of present case involving allegations of sexual abuse¹

The father of two preschool-aged daughters was charged with abusing his children. The statements emerged at the beginning of a long, contentious divorce and custody battle in which the mother sought sole custody based on the children's allegations. The following provides the basic details of the case.

Mr. and Mrs. Smith were married in 1998. They had two daughters, Sophia (born in 2000) and Sally (born in 2002). Around 2001, the couple began marital counseling and at the same time the mother sought legal advice about divorce. In 2005, Mr. Smith left the home with a shared agreement of having three overnight visits per week with his children.

On September 25, 2005, after the father brought the children home, the parents had an argument. The father grabbed his

¹ We have changed all names and some descriptive details to protect the identities of family members and experts in this case.

wife's face and kissed her just before leaving, telling her the marriage was "done." The mother promptly obtained a temporary restraining order that prohibited the father from contacting her or the children. There was no mention of child abuse in the complaint.

On September 26, the mother brought the children to a crisis mental health evaluator (Ms. Kelly), recommended by her attorney. Sophia's (now 5 years 10 months) statements focused on her upset of her parents' yelling at each other. She said, "Mommy says Daddy is mean"; and that she would be sad if she couldn't see her father, but if she had to, she would choose her mother. Sally provided no information except that her father stopped the family credit card. (Sophia also made a similar statement.) Thus, 24 hours after they had just seen their father, the children did not allege sexual abuse nor did they exhibit any behaviors that caused the evaluator to suspect abuse.

The next day the mother called the school to inform them of the restraining order. At that time, she first expressed her concerns about sexual abuse. It was recommended that the school's crisis counselor (SG) interview Sophia.

On September 28, during a 45-min unrecorded interview, Sophia allegedly told SG in detail how her father had tried to abuse her sexually and how he had abused her sister. She also claimed he put feces in her face. Later in the presence of a school nurse, SG, and a teddy bear,² Sophia claimed that her father digitally penetrated both herself and Sally.

A third interview with Department of Youth and Family Services (DYFS) occurred later that day. Sophia described "bad things" such as yelling, fighting, and hitting. Importantly, she did not report sexually abusive acts.

In the fourth interview on that same day, Sophia was questioned by a detective at the prosecutor's office. During this interview (the only videotaped interview in the case), Sophia's claims were inconsistent and at times fantastic. She denied questions about sexual abuse while at other times making vague claims.

On that same day, the mother asked Sally if anyone touched her "peepee," Sally replied, "it's a secret." Later that day, Sally said that it was a friend. The next day, Sally made no allegations of abuse when interviewed by the detective.

Six weeks later, when the DYFS investigation continued, Sophia claimed that she kissed her father's private parts, that he digitally penetrated her, and all this also happened to her sister. Sally told the DYFS investigator that her father also put feces in front of her face and that her mother hit her with a belt.

December 2005, the father filed for divorce asking for liberal visitation. The mother counterclaimed, alleging the father had sexually abused his daughters. On June 20, 2006, the prosecutors' office decided the case was unsubstantiated and refused to intervene.

July 2006, the mother's attorney phoned psychologist, Dr. Sy, requesting an urgent evaluation of the children who, despite

² Although SG initially claimed that it was a doll, the nurse and police notes indicate that it was a bear. Thus allegations of insertion could not be physically demonstrated.

allegations of sexual abuse, were to begin visitation with their father. Dr. Sy met with the mother for a few minutes and then interviewed Sophia for about 1 hour. At this point, Sophia had no contact with her father for almost 10 months. On the basis of this interview, and on the results of two checklists filled out by the mother, Dr. Sy concluded that Sophia had been abused.

From February 15, 2007 to April 16, 2009, a trial occurred over approximately 50 noncontinuous days concerning the issues of custody and sexual abuse. One of us (MB) was asked by the father to provide an expert opinion on the reliability of these children's allegations of sexual abuse as well as the particular factors that may have affected the reliability of their statements.

Research findings/major principles

The following research findings provide a scientific basis for interpreting the children's allegations in this case.

Preschoolers' reports are often very accurate.

Although preschoolers can remember events and details of experienced events over long periods of time, the age of their earliest memories changes as a function of their age of recall. Thus, according to the most recent review of this literature (Peterson, 2012), on average 6-year-olds can recall information from more than 2 years previously. However, these same memories are not available if the child is asked to retrieve them a few years later. Peterson also summarizes the research on the effects of stress on early recall: children can accurately recall stressful events several years after their occurrence. This characterization of children's memory pertains when they are interviewed by neutral interviewers who question them in a nonsuggestive manner, who test alternative hypotheses, and who have no motive to influence the child's testimony (e.g., Bruck *et al.*, 2006).

Biased interviewers can taint the child's report, rendering it unreliable

The concept of "interviewer bias" characterizes interviewers who hold *a priori* beliefs about the occurrence of events and, as a result, conduct their interviews to obtain confirmatory evidence. In so doing, biased interviewers do not test plausible alternative hypotheses. When children provide such interviewers with inconsistent or bizarre evidence, it is either ignored or interpreted within the framework of the biased interviewer's initial hypothesis.

Biased interviewers' beliefs are transmitted to the child through a range of suggestive techniques that are associated with the elicitation of false reports. Consequently, the child may come to inaccurately report the belief of the interviewer rather than the child's own experience. Finally, the concept of a biased interviewer is not limited to forensic interviewers but may also include therapists, teachers, and parents (see Bruck *et al.*, 2006 for a review).

A study by Bruck *et al.* (1999) showed how interviewer bias can quickly develop in natural interviewing situations

and how children will adopt the belief of the interviewer and wrongly report that they experienced an event. Importantly, interviewer bias also affects the memories and reports of the interviewers. Thus, even if a child correctly denied engaging in an experience which the interviewer believed had occurred, the interviewer will later report that the child, in fact, had engaged in that experience.

Biased interviewers use suggestive interviewing techniques

Interviewer bias influences the entire architecture of interviews as revealed through a variety of suggestive interviewing techniques. In the present case, we identified the undue presence of six techniques that also occurred in suggestive interviews in a range of cases involving child witnesses and consequently have been the subject of scientific study.

Specific questions

Asking the child “yes”/“no” questions (Did he do that?) or choice questions (Did he do A or B or C), or “loaded”/leading questions, (Her mom told me that happened to her, did it happen to you?) are particularly problematic when interviewing young children. These not only force the child to provide an answer but also indirectly give the child information about the suspected event or the interviewers’ beliefs—thus, they are termed suggestive. One of the major problems with such questions is that young children rarely reply “I don’t know” when questions are nonsensical or very misleading (e.g., Fritzley *et al.*, 2013; Waterman & Blades, 2013). This is true even when they have been enjoined to say they do not know if they are not sure about something.

It is because of their poor performance on such questions that general guidelines for interviewing children emphasize the importance of asking open-ended questions (e.g., Tell me what you did today) to allow children to describe their experiences in their own words (e.g., Lamb *et al.*, 2008).

Repeated specific questions within interviews

When children first deny the occurrence of an event, they will often change their answers if these same types of questions are repeated (Poole & White, 1991; Krähenbühl *et al.*, 2009). Of particular concern is the finding that this pattern is more likely when children are asked misleading questions (about events they have not experienced). Thus, repetition of questions not only provides the child additional misinformation but can also result in shifting their initial accurate answers to inaccurate answers.

Repeated suggestive interviews

There are also adverse effects of repeating suggestive information (through the use of a variety of suggestive techniques, including asking specific questions) across multiple interviews (e.g., Bruck *et al.*, 2002; Erdmann *et al.*, 2004). Specifically, with each repeated suggestive interview, children are more likely to assent to previously denied nonexperienced events and these reports persist when children are later questioned by a neutral interviewer.

It is also the case that if children provide new information with repeated suggestive interviews, there is a high probability that it will be false (Pipe *et al.*, 1999; Salmon & Pipe, 2000), even if children are suggestively interviewed about true events (Bruck *et al.*, 2002; Scullin *et al.*, 2002). When interviewers urge children to tell them more, these requests sometimes result in false reports by the children to comply with their perception of the interviewer’s wishes. Often these false reports are highly detailed, even more so than true reports (see Bruck *et al.*, 2002). Thus, in a suggestive interviewing context, the presence of many details is unrelated to accuracy.

It is also important to keep in mind that in some contexts repeated interviews can have positive effects on children’s recall of an experienced event by providing them with additional opportunities and time to recall additional details; this is especially true if the interviews are nonsuggestive and occur close to the experienced event (La Rooy *et al.*, 2010).

Stereotype induction

Suggestions do not always take the form of explicit (mis)leading questions, such as “Your Dad was mad, right?” A more subtle strategy of conveying the same information is to insert (often negative) characteristics about a person into the conversations, that is, vilification. A variety of studies have shown that when children are provided with information that a person does “bad things,” they will creatively incorporate this into their own reports of wrongdoing (e.g., Lepore & SESCO, 1994). For example, when children were told that a man who visited their preschool was clumsy, they often later claimed to have observed him doing clumsy things like breaking toys (Leichtman & Ceci, 1995).

Peer contamination (cowitness contamination)

Although adults are usually the suggestive source, children (peers, siblings) can also contaminate each other’s reports through natural conversations. Principe and Schindewolf (2012) have shown that young children will pick up information about an event from peers and even though they have never experienced this event, will elaborate it and later claim it also happened to them. Their false claims are indistinguishable in many ways from true claims made by other children.

Nonverbal props

Because of young children’s limited language skills, nonverbal props (dolls, toys) have been used as a tool to question children who witnessed crimes, including those suspected of having been abused. Although the use of props seems intuitively useful, the scientific literature indicates they can be suggestive, particularly for younger children; they result in increased false reports about touching (see Poole & Bruck, 2012). A major reason for this is that children use the props as toys to play with and to explore, rather than to demonstrate experienced actions.

Although each suggestive technique is associated with error, the risk for false statements is greatly augmented when interviews contain a combination of different suggestive techniques

(e.g., leading questions, peer pressure, vilification through stereotype induction), which increase the salience of the interviewer's bias (see Ceci & Bruck, 1995; Bruck *et al.*, 2006 for details and examples).

The first interview with a child provides the most reliable testimony

When children are interviewed over time, the general rule is that the statements in the first interview are the most reliable. This is because, compared to later interviews, there is less chance for forgetting, and less opportunity for suggestive and other influences to taint children's reports. However, if there is suggestion in the first interview or in conversations prior to it, the child's initial statements may be tainted and therefore unreliable.

Thus, in documenting the evolution of children's allegations, it is important to determine if (a) the child's first statement is spontaneous, unprompted, and made in the absence of previous suggestive elements, or (b) the first statement is associated with previous or concurrent suggestive interviewing techniques.

Suggestive interviewing techniques can result in false beliefs that are longlasting

Children may come to believe that they actually experienced false suggested events. Thus, asking them to tell the truth, to tell only what actually happened, or to say "don't know" when they are unsure, can be fruitless (Poole & Lindsay, 2001; Principe & Schindewolf, 2012) and will not detain their reports.

A corollary of this principle is that once a child's statement has been tainted, it may be impossible to untaint it in subsequent interviews, regardless of the skill of the interviewer. In subsequent nonsuggestive neutral interviews, children will make spontaneous disclosures sometimes with many details about events that are thematically related to prior suggestions. They will do this even when a subsequent interviewer attempts to talk them out of their false statements or warn them that what they heard was untrue (Leichtman & Ceci, 1995; Erdmann *et al.*, 2004). No amount of probing and deprogramming can unearth the original, untainted memory because it may have been irrevocably modified by the prior suggestive questions and become a false belief, that is, part of the child's autobiographical memory. Recent evidence also shows that even after mildly suggestive interviewing has ceased for many months, children will still continue to make false reports (Akehurst *et al.*, 2009; London *et al.*, 2009; Price & Connolly, 2013).

Children's false reports can seem credible

Some professionals state that they can detect the effects of suggestive questioning because the children parrot the words of adults who interviewed them. However, evidence from the past decade provides no support for this assertion. First, children's false reports are not simply repetitions or monosyllabic responses to leading questions. Under some conditions, their answers go well beyond the suggestion and incorporate

additional nonsuggested details and emotions (e.g., Bruck *et al.*, 1995, 2002). In fact, in some studies, children's narratives of false events contain more embellishments (including descriptive and emotional terms) and details than their narratives of true events (Bruck *et al.*, 2002). False narratives often contain more spontaneous statements than true narratives. Although for the most part the details in false stories are realistic, they often contain more bizarre details than true narratives (Bruck *et al.*, 2002; Powell *et al.*, 2003).

Relatedly, subjective ratings of children's reports after suggestive interviewing reveal that they appear highly credible to prospective jurors or trained professionals in the fields of child development, mental health, and forensics (e.g., Leichtman & Ceci, 1995; Laimon & Poole, 2008); these professionals cannot reliably discriminate children's accurate reports from suggestively induced inaccurate reports. In many of these studies, the children who provided the false reports spoke sincerely and provided accounts laden with emotion and perceptual details and used body language consistent with their reports. In summary, there are no scientifically acceptable markers for judging the child's truthfulness in interviews that have been preceded by suggestive interviews.

Electronic recordings of the full interview must be obtained in order to determine the degree of bias and suggestiveness of the interview

It is important to have an accurate verbatim record of everything that the child and the interviewer said. Although it may be impossible to electronically record all interviews and conversations (including ones with parents and peers), at the very least all forensic interviews should be recorded (see Bruck *et al.*, 1999).

The reason for electronic recording is because interviewers/observers cannot accurately write down all of the interactions and exact words of an interview. Notes of interviews omit many details and utterances that the recorder simply misses or deems unimportant. For example, the note may omit all instances where the child provided no information in response to questions, and may only contain information about details that the interviewer considers important to the investigation. (Cauchi *et al.*, 2010). Recorders also make mistakes in describing how statements are elicited; a common error is to claim the statement was spontaneous when, in fact, it was a monosyllabic response to a set of repeated leading questions (Bruck *et al.*, 1999; Warren & Woodall, 1999). When asked how specific information was obtained from a child, most interviewers erroneously reply that they never use leading questions when in reality they rely on them heavily (see Lamb *et al.*, 2000). Recorders, especially those with specific biases, also misinterpret or misperceive children's statements: even though a child may fail to confirm an interviewer's belief, the interviewer may nonetheless later inaccurately report that the child made a statement that was consistent with the belief (Bruck *et al.*, 2006).

Scientific analysis of the facts of the case

Sources of information about the children's reports

The only interviews that were videorecorded were those conducted with Sophia (September 28) and Sally (September 29) at the prosecutor's office. There was no electronic recording of SG's interview that elicited Sophia's first allegations of abuse (on September 28) and SG could not take notes due to a broken thumb. There is an audiotape of Sophia's interview with Dr. Sy but it is of such poor quality that Dr. Sy had to use her notes to produce a transcript. Thus, the following analysis of these interviews is made without reliable information on their structure or content. It is unknown how many of the children's statements were omitted or misinterpreted or if suggestive techniques were used to elicit them. Finally, the court ruled that the mother's diary notes were often manufactured or edited in anticipation of the upcoming trial.

Here we provide examples from the case materials of the children's allegations. We have edited these greatly to reduce the salacious language used by the children. We however do provide some examples because the statements in this case are similar in terms of their shock value to those in many cases that we have assessed. Also, it is important for the reader to appreciate the types of statements that are elicited in the context of interviewer bias and suggestive interviewing techniques.

The role of bias in the evolution of children's initial disclosures

Mother

Biased interviewers may have a conscious or unconscious motive to tilt children's testimony. This seems to have been the case for Mrs. Smith who had been actively seeking advice about divorce for several years before Sophia's disclosures. Months before Sophia's allegations of CSA, Mrs. Smith expressed concern (according to her diary entries) that the children may have been abused or were at risk for abuse. Further she was concerned that her husband might gain custody. Mrs. Smith relayed these concerns to her children and their interviewers in a variety of ways. For example,

- She repeatedly told the girls that nobody should touch their private parts and that if this happened they should tell her.
- She estimated that she had discussed sexually abusive activities with both of her children approximately 90 times between September 25, 2005 and August 2006. These talks also included the "bad things that daddy did."
- Prior to the children's first interview with the crisis counselor, on September 26, she discussed the prior day's incidents involving their father with the children and corrected Sophia's recollections.

SG (The school's crisis counselor)

Before interviewing Sophia on September 28, SG had a phone conversation with Mrs. Smith who provided details about her

husband's sexual violence, about her concerns about Sophia, particularly in light of what she felt were highly inappropriate and sexualized behaviors on the part of both Sophia and her husband. (Sophia probably heard the mother's side of the conversation.) Armed with this background, SG began her interview with Sophia.

Suggestive techniques on September 28

Although the SG interview was not recorded, there are a number of hints that throw some light on the atmosphere and interactions during this interview:

At the beginning of the interview, Sophia needed to go to the bathroom where the interview continued. As Sophia was on the toilet moving her bowels, she said that she had a really big secret that only her mother knew about. Instead of waiting to question her until they returned to the interview room, SG coaxed Sophia to tell about the secret. As Sophia exited the toilet stall, she took paper towels from SG's hands, crumbled them up and reported that Daddy puts feces (poop) in her face. Thus, the claim about feces being put in her face arose in this toileting scenario, not in a neutral forensic context.

Next, Sophia made a number of unusual allegations, for example, the father made her touch his private parts with a towel and then with a broom stick and he was wearing a business suit when he scooped the poop out of the toilet. The lack of follow-up questioning about these allegations reveals SG's belief that Sophia was telling the truth. Finally, although Sophia said she had run away when her father tried to touch her, she said she had seen him poke Sally's genitals with his fingers (in response to a leading question), and that she saved Sally. She was not asked how she did this nor was she challenged to explain seemingly implausible allegations.

Later, in the nurse's office with SG present, Sophia was given a bear and asked if she had been hurt and to show on the bear how. Sophia proceeded to hit the bear repeatedly. When asked if her father hurt her anywhere else, she demonstrated by poking the bear between the legs and said that her father did that to Sally, too.

A number of factors compromised the reliability of these reports. First, they were based on SG's memory, which changed as she reported this incident over time (e.g., SG claimed that a doll was used and not a bear). As discussed, adults are unable to accurately reconstruct verbatim accounts of what children told them even minutes following an interview, often misremembering the number of times a question was asked, its content, and the nature of the child's answers. The reliability of Sophia's allegations was also compromised by (i) the inappropriateness of questioning her during a toilet break; (ii) the possibility that the towels, along with the activity of having a bowel movement, prompted this child to make a report based on them; (iii) the possibility that these reports were not spontaneous but emerged as a result of constant questioning about the "secret." (Sophia later told another interviewer that there were hundreds of questions.) It is often found that when children are repeatedly

questioned and feel pressured to answer, they will alight on something that captures their attention (as seen in transcripts of laboratory studies, e.g., Bruck *et al.*, 2002). Perhaps if Sophia had been interviewed in a cafeteria she would have seized upon a bowl or utensil and woven this into her narrative. (iv) the lack of follow-up questioning about Sophia's bizarre allegations revealing SG's firm belief (as reflected by her statement that she was certain that Sophia was telling the truth); (v) the first report of sexual touching was enacted on a prop (a bear) in response to repeated suggestive questions. These factors, along with SG's prior information about the mother's concerns that were also overheard by Sophia, render Sophia's statements unreliable.

In the early evening of September 28, 2005, Sophia was interviewed for the fourth time that day.³ At the beginning of the interview, she reported that she had fun with daddy at his house but she was also aware that her mother was watching out for wrongdoing on his part. She did not make any derogatory statements about her father during this part of the interview.

When asked what she had talked to SG about, Sophia reported the incident of yelling and grabbing from Sunday, September 25. She claimed that Daddy was mean and he hit her. She said that her father tried to touch her private parts, but he never touched her or her sister. When prompted to tell more about what she had told SG, Sophia said, "I can't ... because there was 100 questions." Sophia was very distracted and asked for the questioning to stop.

Still, the detective pursued her with repeated and pressurized request for more information about what she had told SG: "What did you tell her?", "What did you show her?", "Did you talk to SG and the nurse about daddy touching your peepee?" This is highly problematic because the task for Sophia became one of remembering what she told SG and the nurse rather than remembering what, if anything, really happened.

As now shown, it was the use of repeated questions that provoked an ambiguous response from Sophia that she was touched. She initially denied that her father had touched her private parts. To many repeated questions about what she showed on the bear, she either was silent or else replied that she showed how Daddy had hit her. Finally, Sophia was asked, "Poked you where?" at which point, she pointed to her stomach and her crotch. This interaction is significant because Sophia's nonverbal gesture was made in response to a leading question and to the directive to tell what she showed SG and the nurse. The response was also made after she was asked a number of similar questions where she denied touching or did not respond. When she was directly asked about the "poopy," Sophia didn't want to tell, repeating that it was a secret with her mother. During this period she was bombarded with questions and told that she could not see her mother, despite her many requests to leave the room. Thus, any of Sophia's statements could be a consequence of trying to please the interviewer (rather than report what actually happened) and to escape this aversive situation.

³ Recall, that in the third interview with DYFS, Sophia made no sexual allegations.

November 2005 interviews

Six weeks after their last contact with their father, the two children were interviewed by DYFS. Their statements differed considerably from those made in September. First, Sally reported that her father had put poop in her face and that her mother had hit her with a belt.

Sophia now claimed that she did kiss her father's private parts, that he digitally penetrated her, and that these things happened to her sister, too. She claimed that the poop incident had happened at both parents' houses. Sophia stated her father should go to jail, evidence of a growing negative stereotype.

Although the children's new reports of sexual abuse may reflect a growing comfort and support in disclosing actual events, they are equally likely to reflect the repeated suggestive conversations with their mother and interviewers. This hypothesis was also raised by one of the November interviewers who expressed concern about the effects of the prior interviewing on the accuracy of Sophia's statements.

Evidence of peer contamination

Although Sally had yet to make any reports of sexual abuse to professional interviewers, her mother's diary included many such allegations. These were remarkably similar to those made by her sister and raise the concern that the children contaminated each others' reports. For example, one child reported a nightmare and the other child stated that she also had that one. In November, Sally's allegations of "poop" and being hit also mirror those of her sister.

Reports of hitting and of scatological behavior

Sophia's (and Sally's) first allegations involved hitting and also touching poop. We have observed this pattern in many cases in which young children are suggestively interviewed; often these reports precede more explicit reports of sexual abuse (e.g., New Jersey v. Michaels, 1994 and others). One interpretation often given by clinicians is that children begin to disclose abuse by describing the least abusive incident, which allows them to gauge the reactions of their interviewers. Some experts have claimed that scatological reports are consistent with the behavior of sexually addicted perpetrators, although there is no empirical evidence for this claim. Another interpretation that is consistent with research on stereotype induction (e.g., Ceci & Bruck, 1995) is that when young children are relentlessly asked to tell "bad" things about a suspect, in order to please their interviewers they think of the worst things within their realm of knowledge or fantasy—namely, physical abuse and scatological subjects. For example, Mrs. Smith recounted that Sophia's fear that her father would do "badder" things to her such as pushing her down the stairs.

This also leads to the conjecture that Sophia may have made allegations of sexual abuse without truly understanding the content of her statements, as further illustrated when Sophia said that she hadn't told her earlier of her father's bad acts because she didn't know they were bad. Then she asked her mother, "Why is it so bad?"

In summary, by definition, all reports provided by Sophia and Sally after September 26, 2005 were unreliable and tainted. Sophia's statements on September 28 were responses to "hundreds of questions" in both the school and police interviews. The idea of digital penetration seemed to emanate from being asked to show on a bear where she and her sister were touched. Furthermore, given the turmoil between parents that sometimes involved the children, including witnessing her father grab her mother and knowing that the police were called to protect her mother, it is not surprising that Sophia's major reports involved hitting, yelling, and descriptions of a mean father.

Thus, 6 weeks after the first allegations, Sally had yet to make an allegation of sexual abuse and Sophia's allegations were inconsistent with what she had previously reported (some details were added and others were omitted). New reports or changed reports that emerge in the context of suggestive interviewing have a high probability of being false (as reviewed). Consistent with this reasoning, the prosecutor's office decided that the case was unsubstantiated. Thus, based on legal, scientific, and clinical grounds, there was no reasonable foundation to interview the children about abuse again. Nonetheless, the interviewing did continue.

Dr. Sy Interviews Sophia on July 19, 2006, 10 months after her last contact with her father

Sophia readily engaged in conversation with Dr. Sy and without too much prompting revealed that she had to touch her father's feces and lick his private parts and Sally poked her with her finger. She also stated that Sally lied and she only saw her father hit Sally on her buttocks. Dr. Sy's diagnosis of child abuse was based on Sophia's spontaneity, credibility, and physiological reactivity while relating some of the events.

In general, experts in this case discounted the potential effects of any previous suggestion because Sophia's later disclosures were so credible and so consistent with previous reports. They also stated that her lack of contact with the perpetrator minimized false recantations and increased the probability of true disclosures. The experts also agreed that because Dr. Sy's interviewing techniques were impeccable, she could not only extract true disclosures but also evaluate the degree to which they were a product of coaching. All agreed that her interview with the child was neutral and nonsuggestive. In the remainder of this chapter, we discuss these and other claims in light of the scientific research literature.

Dr. Sy's recording and reporting techniques

Dr. Sy used a voice-activated audio recorder that kept shutting off during the interview and needed to be turned back on. She claimed that she was also taking contemporaneous verbatim notes, and used these to fill in gaps in the transcript of the interview.

Having to monitor the functioning of a machine, scrupulously observing nonverbal actions, and at times using props (such as dolls), would likely make it impossible to write virtually

everything asked and answered. Furthermore, the claims that she could verify the child's trauma through body language such as "gag reflex" and holding her crotch (a sign that the child was in pain) are nonverifiable without a video record of this important interview.

Dr. Sy violated important interview guidelines

Dr. Sy portrayed her style as one of neutrality and nonsuggestiveness. She bolstered her neutrality by stating that she went into the interview "cold"; meaning that she did not review the previous records or speak to any of the previous professionals.

However, reviewing all records and sources is a cornerstone of good interviewing practices. Without this, she could not test hypotheses about the source of or influences on the child's statements. Thus, one is left with the paradigmatic model of an interviewer who has one major hypothesis and does not rule out competing ones. It turns out, however, that Dr. Sy did not go into the interview "cold"; she had spoken with the mother's attorney and with the mother who related the details of her sexual history with the father, among other things. Furthermore, it is clear in part of the interview that Dr. Sy knew some of the prior allegations because she asked questions about some of the content before the child had said anything. (In fact, Dr. Sy later did admit that she did know the content of the child's allegations.)

Despite her statements that she conducted a "state-of-the art" interview that would allow her to elicit the truth from the child and to avoid suggestions, this was not what occurred.

She used dolls to elicit a new allegation of penetration. Many of the current protocols discourage the use of dolls for young children and all warn of their potential suggestive powers. Because this interview was not recorded, it is unknown if the dolls were anatomically detailed; even if they were not, as we explain here, the use of dolls to elicit sexual information from children is very suggestive and can taint children's reports (Poole & Bruck, 2012). The following interaction in which Dr. Sy tried to get Sophie to elaborate shows how dolls can interfere with the reliability of a child's statements.

- Sy: If this were him and this were you, show me how he did that? (*she gives her a doll*). This is him and he is sitting just like this and this is you. Show me how he put you. I don't get it. He is sitting and you are standing and then what?
- Sophia: And then he pushed me down
- Sy: And then what?
- Sophia: He was on the couch.
- Sy: I don't see any pee pee's touching. I don't see pee pee's touching. Show me how the pee pee's started to touch. But I want you to just show me with the dolls. You are laying there and how does he get his pee pee to touch your pee pee, I still can't figure it out.
- Sophia: Standing up, standing up, standing up (*demonstrates with two dolls*).
- ...

Dr. Sy: Now how did that feel when that was touching that?
How did that feel?
Sophia: It was actually poking inside it.

Here we see why dolls/props are suggestive. Dr. Sy repeatedly demanded that Sophia show sexual touching on the dolls—a strategy that was associated with Sophia changing her initial response from “laying on the floor,” “to sitting on the floor,” “to standing.” The latter is physically impossible for a man and a young child, but is nevertheless accepted by Dr. Sy. This is the first time, 10 months after the initial allegations, penile penetration is reported.

In other sections of the interview, Dr. Sy also used a number of leading questions and Sophia conceded to these rather than sticking with her original stories.

The experts vouched for the truth of Sophia’s reports

Contrary to the scientific evidence, experts in this case remarked on the credibility and truth of the Sophia’s statements. Dr. Sy’s conclusion that Sophia was abused was based in part on the consistency of her reports. One expert claimed that most of Sophia’s reports were consistent over 10 months. To the contrary, except for the consistency of her reports touching feces and hitting, her reports were not consistent but changed remarkably over time. Initially she told SG that her father tried to touch her and she saw him poke Sally. It was not until the November interview that she disclosed the sexual experiences. Much later she told Dr. Sy further details such as genital insertion, and she only saw her father hit her sister’s butt. Given the amount of suggestion and discussion with the mother and her sister that has occurred over a period of 21 months, a major hypothesis is that these reports were suggestively induced.

The experts claimed that Sophia’s reports were accurate because they were spontaneous and thus could not have been coached. The scientific literature supports the view that spontaneous reports in response to open questions are a good marker of children’s accuracy. However, this is only if reports are free from previous or concurrent suggestive techniques. In much of the literature reviewed in this chapter, as a consequence of suggestive interviewing, children’s subsequent reports become spontaneous, consistent, and detailed—albeit inaccurate. Sophia’s narratives with Dr. Sy conform to the expected pattern of children whose reports emerge as a consequence of suggestion. This is not to imply that they are demonstrably inaccurate, only that their accuracy cannot be assumed.

The experts also dismissed the hypothesis of suggestion by claiming that there was no evidence of coercive interviewing or that the interviewers provided them with sexual information. Although there is reason to believe that the children were exposed to a highly suggestive environment where their father was vilified and where they were constantly engaged in conversations of abuse, taint could also occur in situations that were less toxic. The literature has shown that even after one or

two suggestive interviews children can develop false memories about salient but nonexperienced events.

Also inherent in the experts’ denial of the role of suggestibility was the view that it would be impossible to suggest sexual abuse to children who can only be led to make false reports about unemotional, unimportant events. Both views are incorrect. For example, in a series of studies, Otgaar and colleagues have implanted false memories in children by telling them their mother or teacher described an event that happened to the child in the past. Sometimes extra details were provided (showing the child a photograph or giving them more knowledge about the event). Using these rather mild short-lasting procedures, these researchers found significant rates of false memories for viewing a UFO (Otgaar *et al.*, 2009), receiving an enema (Otgaar *et al.*, 2010), and being caught by their teacher for cheating (Otgaar *et al.*, 2008).

In addition, there have been a number of studies in which children have been led to make false allegations about bodily events which, were they to occur in the real world, could result in criminal investigation. For example, children have made false claims about “silly events” that involved body contact (e.g., “Did she blow in your ear?”), which persisted in subsequent interviews over a 3-month period (Ornstein *et al.*, 1992). Children falsely reported that a man put something “yuckie” in their mouth (Poole & Lindsay, 2001), that their pediatrician inserted a finger or a stick into their genitals (Bruck *et al.*, 1995), and that a man touched their friends, kissed them on the lips, and removed some of their clothes (Lepore & Sescio, 1994). A significant number of children falsely reported that someone touched their private parts, kissed them, and hugged them (Goodman *et al.*, 1991; Bruck *et al.*, 2000). Children assented to suggestions that a doctor cut a bone in the center of their nose to stop the bleeding (Quas *et al.*, 1999). Finnila *et al.* (2003) reported a significant number of 4- to 8-year-olds falsely assented to misleading questions about keeping a secret, being touched, and having their picture taken. Children have also elaborated their false narratives with emotional terms (e.g., “It hurt”; “I cried”; “I was happy,” see Bruck *et al.*, 1995, 2002). Finally, some research has found that it is easier to create a false memory for a negative event than for a neutral event (Otgaar *et al.*, 2008). Thus, the suggestibility literature is a valid basis for evaluating the possibility that suggestive interviewing can result in false allegations about emotionally evocative events, including, but not limited to, bodily harm.

In order to examine the reliability of the children’s disclosures, one must follow the general principles described in this article. Specifically, the first interview with the crisis counselor, Ms. Kelly, on September 26, 2005 is the most reliable. Although the first interview did not focus on sexual abuse (the interviewer did not see any signs of abuse), it is important to note that this interview occurred closest to a very unpleasant event (parental fighting) when the children’s memories were freshest. Sophia described that event clearly, but did not report any other significant negative events concerning her father. At this point, the

mother had not communicated suspected sexual abuse that she supplied in the following days. Her relative lack of interference at this point may have produced the most neutral interview and the most reliable statements from the children.

Epilog

The judge barred Dr. Sy's testimony and report from the court proceedings. "Dr. Sy's methodology was not based on generally accepted science. Among other deficiencies, Dr. Sy also failed to test alternative hypotheses, record the interview, and generally failed to consider the totality of the circumstances leading to (Sophia's) interview." The judge also ruled that for all the reasons stated in this report that Sophia would not be allowed to testify, namely, because her testimony was potentially tainted. The judge issued a final judgment of divorce, awarding the father sole custody of his two daughters.

Beyond issues of sexual abuse

In this chapter we have focused on a case of alleged sexual abuse; however, the very same issues, guidelines, and scientific frameworks apply across a wide variety of situations when children are interviewed by adults. These include legal contexts in which the child is a potential observer or participant, such as claims of physical abuse or being an eyewitness to a crime. These issues are particularly important in the psychiatric milieu where the child is often the primary provider of information. Professionals must be aware of their own biases and attempt to question children in as neutral fashion as possible and above all to test alternative hypotheses.

Introduction

Some children cannot be cared for by their biological parents or other relatives, so unless private arrangements are made, the state has to find a way to care for them. The reasons for coming into public care vary across individuals, societies, and time. Some parents are unable to look after their children through illness, death or disposition; others, especially historically, could not due to poverty or due to the stigma in case of children born out of wedlock; the majority in developed countries now come into care due to neglect or abuse. The proportion of children in public care varies by country; for example, in England it is around 0.5% of the child population, about 60,000 children, (Department for Education, 2013), whereas in the United States it is around 1% of the child population, about 500,000; about a fifth of these are in residential care, but with considerable variability by area/state (Children's Bureau, 2013). Many stays in public care are brief; in any year, about half of the children seen in the care system will have entered or left it. We define foster care as living with unrelated parent figures who provide care and take responsibility in a similar way that a birth parent would, but without full and final legal responsibility. As with parents who do have such responsibility, there may be a mother figure, a father figure, both, or other combinations, and there may be other children in the family. In contrast, in residential care, there is usually no one taking on the more committed, intense, and exclusive role that a parent does. Instead, there are usually a number of care staff, none of whom typically has primacy or an especially close relationship; usually they leave as time goes by and are replaced by new workers.

There are several types of residential care. In many countries, babies who cannot be looked after by their parents or immediate family are put into orphanages, and much of the section on residential care refers to this context, which is now less common

in high-income Westernized countries, but is not uncommon in some eastern and southern European countries and other parts of the world. In countries where the prevalence of AIDS is high, particularly in sub-Saharan Africa, the number of children being orphaned is going up rapidly, and many are being taken into institutional care (see Chapter 46); it has been estimated that there are 143 million orphans worldwide (Whetten *et al.*, 2009), with an estimated 8 million children in residential care. A second, different kind of residential care that we discuss occurs where children cannot be looked after by their parents and prove too difficult to be looked after by foster carers. Such children often have relatively severe behavioral problems, and are more often adolescents. This form of residential care is common in high-income Westernized countries, and in the United States may be called group-care homes. A third type of residential care is that given to young offenders (see Chapter 49), a fourth is inpatient child and adolescent psychiatric units (see Chapter 50); also, there are residential schools for children with emotional and behavioral disorders.

Residential care

The nature of residential care

Residential care of children whom biological parents are unable to care for is widely used across the world, and its nature varies both between and within countries. Gunnar (2001) defined three levels, based on quality: (1) institutions characterized by global deprivation of the child's health, nutrition, stimulation, and relationship needs; (2) institutions with adequate health and nutrition support, but deprivation of the child's stimulation and relationship needs; and (3) institutions that meet all needs except for stable, long-term relationships with consistent caregivers. Logically, it is possible to add a fourth level, namely, an institutional environment that provides for stable and consistent

caregiving (Van IJzendoorn *et al.*, 2011). Some organizations try to provide this (The St. Petersburg-USA Orphanage Research Team, 2008; SOS Children's Villages, 2013).

However, in typical residential care, group sizes tend to be large, typically 9–16 children per unit, and the number of children per caregiver can be very large, from 8:1 to 31:1 (Van IJzendoorn *et al.*, 2011). Groups tend to be similar with respect to child age and to psychological or physical disability status. Children are periodically “graduated” from one group to another, with separation from potentially trusted group workers and peers. Continuity of carers is often compromised as professional group workers tend to change frequently because of high staff turnover; workers may work long shifts and then be off for some days; they may not be always assigned to the same group; and they are of course entitled to vacations. The result is that a child may see anywhere between 50 and 100 different caregivers in the first 19 months of life (McCall *et al.*, 2011) and older youth in residential care may not fare better.

An example of an institutional rearing setting that is characterized by many of the features described above—at least up until 10 years ago—is the *Metera Babies Center* (MBC), in Athens, Greece. Most MBC infants come from settings in which they are at high risk for neglect or abuse, relinquished shortly after birth by parents who are unable to provide for them (Vorría *et al.*, 2003). After a few months, infants are moved to pavilions housing children ranging in age from 5 months to 5 years. MBC provides adequate nutrition and health care but lacks stability in child–caregiver relationships and does not provide a playful and cognitively stimulating environment. In the unit for newborns, social contacts and interactions are very restricted. Each newborn is placed alone in a separate small room. One caregiver is responsible for as many as seven infants; caregivers limit their attention to feeding and cleaning the babies. Subsequently, when the babies move to the pavilions, they are housed in groups of 12 children who are looked after by 12 caregivers in total. Thus, in theory the infant/caregiver ratio is 1:1, but in practice, due to the 24 hour shifts, the actual ratio is 6:1, as each caregiver has to look after 4–6 infants at the same time. On a regular day, infants spend a total of 3½ hours playing and 17½ hours in their beds. During weekends and holidays, fewer caregivers are available. Although books and toys are available, the caregivers do not have enough time to interact with the infants using these materials in a stimulating way (Vorría *et al.*, 2003; Van IJzendoorn *et al.*, 2011). Many of the caregivers are not adequately trained for their jobs and their interactions with the infants were less sensitive than those of biological mothers in a comparison group of family-reared infants (Vorría *et al.*, 2003).

The “prototypical” institution described inevitably deprives children of sensitive reciprocal interactions with stable caregivers. In this respect, many institutions are characterized by *structural neglect*, which may include minimum but sufficient physical resources, unfavorable staffing patterns, and inadequate caregiver–child interactions (Van IJzendoorn *et al.*, 2011). Structural neglect should be located at the extreme end of the

cumulative risk continuum, and as such it may be considered a special case of child maltreatment (Cyr *et al.*, 2010).

Development of children raised in institutional care

Children raised in residential care settings often suffer from marked developmental delays and may follow deviant developmental pathways. However, the various causes of these delays are difficult to disentangle. First, in some instances, it is difficult to know whether the institutional experience actually causes the deficits or simply maintains preexisting deficits. Second, the forms of deprivation experienced by institutionalized children rarely occur in isolation (Van IJzendoorn *et al.*, 2011). Here we present the (often severe) commoner developmental deficiencies that most institution-reared children display; others are described by Nelson *et al.* (2011).

Physical growth

Children who spend the first few years of their lives in institutional care often show retarded physical growth on parameters such as weight, height, and head circumference. In a meta-analysis of eight studies ($N = 893$), institutional stays prior to adoption were strongly and linearly associated with reduced height ($d = 1.71$), a dose–response relationship, illustrating the potentially causal, negative effect of institutional care on physical growth (Van IJzendoorn & Juffer, 2007), which persists through adolescence (Sonuga-Barke *et al.*, 2010).

Hormonal (HPA axis) development

Atypical patterns of diurnal cortisol activity for children living in institutions were first reported by Carlson and Earls (1997). None of the children exhibited a normal pattern of cortisol variation (high morning and low evening values). Instead, they showed low morning values and slightly elevated evening levels, a pattern replicated in postinstitutionalized children adopted from Russia and China (Gunnar, 2001). In all these studies showing impaired physical growth and HPA axis development, physical nutrition was judged to be adequate; the cause appears to be related to lack of cognitive and social/emotional stimulation (see also Dobrova-Krol *et al.*, 2008).

Cognitive development

Orphanages can be considered “natural experiments” on the necessary conditions for intellectual growth (MacLean, 2003; Rutter *et al.*, 2012). Recent research continues to show the delayed cognitive performance of children in residential care (Rutter & Sonuga-Barke, 2010; Fox *et al.*, 2011). Van IJzendoorn *et al.* (2008) covered 75 studies on more than 3800 children in 19 different countries in a meta-analysis and found a combined effect size of more than a standard deviation. The children reared in institutions showed on average an IQ/DQ 20 points lower than comparison children. Favorable caregiver–child ratios were associated with smaller cognitive delays, whereas early entry into residential care (before 12 months) was associated

with larger delays. One or more years of family life prior to institutionalization may provide a basis for further intellectual development even when children grow up in a poor intellectual environment later on.

Attachment security

Institution-reared children experience separation from or loss of their birth parents and other caregivers. Institutionalized children show high rates of insecure and disorganized attachment, for example, rates of security were 17% versus 62% in family-reared children, with most extra insecurity in the form of disorganization: 5% versus 15% avoidant, 5% versus 9% resistant, and 73% versus 15% disorganized (Van IJzendoorn *et al.*, 1999; see Chapter 6).

The rate of disorganized attachment in a residential setting of structural neglect is larger than among maltreated children living in their families, 73% versus 51%, (Cyr *et al.*, 2010). What disorganized attachment means in the context of being raised in an institution remains to be determined (Rutter *et al.*, 2009; Bakermans-Kranenburg *et al.*, 2011a), since there is often a lack of any specific attachment figure; where there is more sensitive caregiving, attachment patterns are more clear-cut (Zeanah *et al.*, 2005; see Chapter 58). Among adolescents admitted to residential treatment settings in West European countries (often due to abuse), most have been found to be insecure and this seems difficult to change in these residential settings (Schleifer & Muller, 2002; Zegers *et al.*, 2008).

Resilience of attachment security in the face of structural neglect

In spite of insufficient sensitive care in residential settings, in some studies, a proportion of children appear resilient. For example, one in five of the Greek institutionalized infants was securely attached with their caregiver. The securely attached infants were found to be “happier,” more social, and to initiate interactions with their caregivers more often (Vorria *et al.*, 2006). It may be that the “happier” infants were more rewarding to interact with, eliciting more sensitive responding from their caregivers, thereby enabling the formation of secure attachment relationships. In contrast, in the English Romanian Adoptee (ERA) study, none of the institutionalized children was found to be securely attached. It is likely that the quality of care in the Romanian institutions was markedly more neglectful and impoverished than in the MBC in Athens. More similar to the Greek rate is the rate in a Chinese institution where 20% of children were rated secure in a study with decreased numbers of children per caregiver to enhance the quality of care (Steele *et al.*, 2009).

The role of genetic factors in resilience under structural neglect is unclear. It would seem likely that infant characteristics would elicit specific caregiving responses which, in turn, could influence the type of attachment security. However, a number of twin studies using the SSP found that the development of attachment security is mostly environmentally

shaped (Bokhorst *et al.*, 2003). A small study of Ukrainian preschoolers reared in institutional settings or in their biological families showed a moderating role of the serotonin transporter gene polymorphism (5HTTLPR). Institutionalized children with the long alleles showed lower levels of attachment disorganization than their institutionalized peers with short alleles (Bakermans-Kranenburg, *et al.*, 2011a). Similar protective effects of the long allele with respect to emotional problems after institutionalization were found elsewhere (Kumsta *et al.*, 2010). Thus, children may differ in their vulnerability to extremely adverse rearing experiences, depending on their genetic characteristics.

Indiscriminate friendliness

One of the most disturbing and confusing behaviors that seems to be typical of institutionalized children is disinhibited or indiscriminately social behavior, characterized as affectionate and friendly behavior toward all adults, including strangers, without the fear or caution that is characteristic of typically developing children. A normative period of indiscriminate behavior is present early in the first year of life. Beginning about 2–3 months of age, infants are quite interested in engaging in social interaction with almost anyone. At 7–9 months, this changes and infants begin to exhibit wariness with strangers. This suggests inhibition of the affiliative motivational system. In children who experience serious neglect, however, the sensitive period for inhibition may close without the development of a selective or specific attachment in the context of a more or less continuous relationship, so that indiscriminate friendliness might persist (Bakermans-Kranenburg *et al.*, 2011b).

In Tizard's study of young children placed in residential nurseries in London in the 1960s (Tizard & Hodges, 1978), all infants experienced residential nursery care for the first 2 years of life, involving a high turnover of caregivers. Subsequently, some went home or were adopted, whereas others remained in institutions. Nearly 38% of the institutionalized children were indiscriminate at age 4 years. A high level of indiscriminately friendly behavior has been confirmed in subsequent studies of institutions (Zeanah *et al.*, 2005; Rutter and Sonuga-Barke, 2010). Interestingly, levels of indiscriminate social behavior appear unrelated to length of stay in the institution and to having a preferred attachment figure or not. Indiscriminate behavior seems more persistent after adoption when institutionalized rearing extends beyond the age of 6 months (Rutter & Sonuga-Barke, 2010; Bakermans-Kranenburg *et al.*, 2011b).

This persistence of indiscriminate friendliness led Rutter *et al.* (2007) to suggest that some form of biological programming may be responsible, whereby the early neglectful environment affects the capacity for focused attention and effortful control. They and others (Bakermans-Kranenburg *et al.*, 2011b) suggest that the core difficulty is a lack of self-control, manifest in social contexts and perhaps also in nonsocial contexts; indiscriminate friendliness was related to inattention/overactivity. This thinking has influenced the change from reactive attachment

disorder in DSM-IV to the DSM-5 condition “disinhibited social engagement disorder” that is related to insufficient care but can be present in children who show no signs of disordered attachment or current neglect (American Psychiatric Association, 2013; see Chapter 58).

Psychopathology

In the Tizard study, those who remained in institutions had higher levels of behavior problems at age 4 (Tizard & Rees, 1975). In adolescence, the ex-institution sample showed high levels of social difficulties (Hodges & Tizard, 1989). Quinton and Rutter (1988) studied outcomes of children who had disrupted early years, were taken into public care and then spent prolonged periods in group homes in the 1960s. Again, the living conditions were satisfactory physically, but there were multiple changes of staff.

In the representative survey of children in residential and foster care who were looked after by local authorities in England by the Office of National Statistics (ONS; Meltzer *et al.*, 2003), nearly three-quarters of children living in residential care had a mental health disorder, compared to 10% in the general population. Children in residential care were twice as likely as those in foster care to have anxiety disorders (16% vs 8%), and four times as likely to have depression (8% vs 2%). Conduct disorders were commoner too, 56% versus 33%, as were autistic spectrum disorders, 11% versus 2%. However, the children had either been placed in residential care because they were too difficult to handle in foster care, or because the units they were in specialized in managing and treating the problem in question, for example, autistic spectrum disorders. Therefore, it would be wrong to conclude that it was the residential care that caused the difficulties.

Benefits and harms of residential care

Can institutional care be as good as family care?

The findings described are universally clear that orphanages that deprive children of a reasonably stimulating environment with opportunities for attachment are harmful, when compared to family or family-like care. However, not all institutions are configured like this, and the Positive Outcomes For Orphans (POFO) project argued that the alternative family care is not always so beneficial. They took orphans or abandoned children aged 6–12 in five low- and middle-income countries and compared institutional care with community care (Whetten *et al.*, 2009). Physical growth and health, as well as emotional and cognitive functioning, were no worse for institution-living than community-living children looked after by families in the wider social network. Indeed, in some domains, institution-living children seemed to fare better. The authors concluded that “institutional care,” *per se*, should not be categorically described as damaging or inappropriate for all children.

However, the POFO study was not a study of foster care, and the majority of community carers were the child’s mother—usually the father had died (Bakermans-Kranenburg & Van IJzendoorn, 2009). Allocation was not random, and pre-

placement differences might have existed. It makes no sense to compare home-reared children with institutionalized children to answer the central question of where abandoned and orphaned children should be placed for whom their biological parent is no option. The quality of community care may have been suboptimal due to the death in the family and the emotional and financial consequences; the countries chosen all had a low human development index. Secondly, 75% of the children came into the institutions over 5 years old, so may have had comparatively normal upbringing in the most sensitive developmental stages. Thirdly, the characteristics of the institutions in the POFO study were very different from those in the studies cited. Many were small and locally organized in response to the need to care for new orphans, rather than large state-run institutions. Last, measurements did not address crucial issues such as attachment and neurobiological development.

Based on the solid set of studies reviewed (and in McCall *et al.*, 2011), it is hard not to conclude that residential settings with structural neglect are pathogenic and should be seen as a type of child maltreatment.

Harmful effects of deviant groups

The notion of peer contagion or deviancy training refers to the idea that if antisocial youth are spending much time together in groups, they may reinforce each other to behave more antisocially (Dishion & Tipsord, 2011). In treatment contexts, however, the validity of deviancy training inevitably being harmful has been questioned; thus, in a meta-analysis by Weiss *et al.* (2005), on 17 out of 18 indices outcomes were no different between individual and group treatments. Nonetheless, there is some evidence for peer contagion in longer term residential care (Lee & Thompson, 2009). Certainly, the survey of residential care described subsequently found a high rate of victimization by other young residents.

Abuse and violence in residential care

Children and adolescents who are vulnerable because of their past experiences with poor parenting and child maltreatment deserve, like all children, to be protected from any sexual or physical abuse. The prevalence of child maltreatment in foster and residential care in the previous year was examined in a representative nation-wide sample of adolescents in the Netherlands in 2010. Based on *professional worker* reports, the prevalence rates of sexual abuse for foster care and residential care in 2010 were 2 per 1000 and 5 per 1000, respectively, but children in foster care were younger and allowing for this, the rates were similar. Compared to children in the general population, children in residential care had a ninefold increase in sexual abuse, whereas the prevalence in foster care was similar to the general population. The estimates based on *youth self-report* were 50–100 times higher: 168 per 1000 children in foster care, similar to the general population, and 280 per 1000 children in residential care, significantly higher (Euser *et al.*, 2013b). Higher rates in residential care may be due to more antisocial behavior at entry,

a peer group culture of reinforcing negativity and emotional and physical bullying, and less emotional commitment from residential workers, who typically receive low pay, little training, and turn over quickly. Likewise, the peer group often turns over quickly, making it hard for the children to develop trusting bonds with other residents. For children who have to be in care, better trained and supervised staff could reduce abuse.

Violence against residential group care workers

In the study cited, 81% of the group workers experienced some type of violence from the children in their care, about half of the participants experienced serious physical violence (Alink *et al.*, 2014). The high levels of violence in residential youth care indicate that residential care may neither be the best workplace for professionals nor the best therapeutic setting for youth. (Euser *et al.*, 2013a, b).

Effects of removal from orphanages to adoptive or foster care

The ERA study (Rutter & Sonuga-Barke, 2010; Rutter *et al.*, 2012) compared adopted children who had lived in severely depriving orphanages until at least age 6 months with a composite comparison group. Of particular interest were four strictly defined deprivation-specific patterns (DSPs): Quasi-autism, disinhibited attachment, inattention/overactivity, and cognitive impairment. Quasi-autism referred to a pattern that showed autistic-like features (particularly, intense circumscribed interests) but which differed from “ordinary” autism in greater social interest and flexibility. Disinhibited attachment involved a disregard of social boundaries and undue familiarity with strangers. Inattention/overactivity had to be persistent and accompanied by one of the first two patterns, as did cognitive impairment (IQ below 80).

Those adopted away from the institution before the age of 6 months showed no deficits at follow up, whereas those who remained in the institution from 6 to 12 months of age showed a large stepwise increase in deficits and no dose–response association with duration of deprivation thereafter. At age 15, 46% of children adopted after 6 months of age had DSPs, versus 1% of controls; DSPs were not mediated by cognitive deficits. The follow-up findings to the late teens indicated that some with quasi-autism showed a fading of autistic-like features but a persistence of disinhibited attachment-like features. Institutional deprivation was not associated with an increase in other forms of psychopathology that were not accompanied or preceded by one of the DSPs. Disturbed peer relations were strongly associated with all DSPs, whereas disruptive behavior was only associated with inattention/overactivity. Emotional disturbances were not increased at age 6, but started to emerge increasingly to age 15; they were largely accounted for by DSPs.

Cognitively, at age 4 years, the children adopted after 6 months had a severely delayed developmental quotient (43 vs 89). Theory of mind, executive planning, and scholastic achievement all showed comparable differences. There was substantial catch up

by the age of 6 (cognitive index 84 vs 106), with further catch up from 11 to 15 years. Those who had definitely not suffered from malnutrition still had very substantial DSPs, suggesting that most of the developmental impact of the orphanages was through psychosocial deprivation (Rutter *et al.*, 2012).

Other studies of internationally adopted children yield similar results, showing massive catch up, but some deficits in those adopted after 1 year of age (Van der Vegt *et al.*, 2009; Audet & Le Mare, 2011). An exception was the British Chinese Adoption study (Rushton *et al.*, 2013). The study group consisted of refugees from China who put their children into institutional care in Hong Kong at the mean age of 3 months and were then adopted into British families at 23 months on average; they were followed up in midlife, in their 40s. On measures of mental health and well-being, there were no significant differences compared to control groups. Possible explanations are that the Hong Kong orphanages were not severely depriving (although the study team give examples of very poor social and emotional care), that the impact of negative institutional experiences may attenuate over decades, and that the quality of adoptive care was better than the care in the control groups. Clearly, more studies that examine these issues and, in particular, that measure the quality of early emotional care, and the effect of several decades of later normal experiences are needed.

In the unique Bucharest Early Intervention Project (BEIP, Fox *et al.*, 2011) children were randomized to stay in institutions or to receive foster care. Their cognitive development was tracked until early adolescence. The three main findings for the first 5 years of the children’s life confirm the meta-analytic findings of Van IJzendoorn *et al.* (2008): first, children reared in institutions showed greatly diminished intellectual performance (borderline mental retardation). Second, children randomly assigned to foster care experienced significant gains in cognitive function. Lastly, the younger a child was when placed in foster care, the better the cognitive outcome. Indeed, there was a continuing “cost” to children who remained in the institution for longer. Overall then, adoption or foster care greatly enhance developmental prospects of most institutionalized children and lead to substantial catch-up growth in most domains (Juffer & van IJzendoorn, 2005; Van IJzendoorn & Juffer, 2006).

Summary of the effects of residential care

In summary, most children raised in institutional care show delays and maladaptation in various domains, including physical, cognitive, socio-emotional, and psychopathological. Not every child is affected in the same way by institutional care, and a small but significant proportion of children show remarkable resilience. Sadly, the majority of institutions worldwide even in modern times create a childrearing environment typified by structural neglect. Residential care for older children who cannot be fostered also does not seem to serve children well; often the climate is violent. Except for cases that cannot be contained despite intensive fostering interventions, residential care would seem to be an undesirable option.

Foster care

Prevalence and nature of foster care

In the United States, there were 410,000 children in foster care in 2012 (Children's Bureau, 2013); in England there were 55,000 children in foster care in 2012, with quite a lot of turnover, nearly half had come into care during the year with a similar number being returned home (Glennendenning, 2012). Foster children are usually placed because of caretaker incapacity or absence, child protection reasons, or parental incarceration. Nowadays, many foster placements include visits with the biological parent (Leathers, 2003; Joseph *et al.*, 2014). Ideally, if conditions at home improve, foster care is not long-lasting and children can be reunited permanently with their biological parent(s). However, in practice there are often frequent changes of placement. In one (not atypical) UK authority in 2012, two-thirds of children taken into foster care were returned within a few months to their birth families, suggesting social workers judged there was an improvement at home, but unfortunately two-thirds of these returners home were subsequently taken back into foster care, adding more separations and turmoil to their lives (Minnis *et al.*, 2010). These figures also show how difficult it can be to assess what is "good enough" parenting.

Development of children in foster care

Hormonal (HPA axis) development

Like other abused children (see Chapter 29), fostered children as a group show blunted early morning cortisol and a dysregulated diurnal pattern (Fisher *et al.*, 2006). Fortunately, good quality foster care can reduce the abnormal secretion patterns so that they become normal (Fisher *et al.*, 2006).

Attachment patterns

A meta-analysis of fostered infants and later placed foster children has shown that they are as securely attached to their foster carers as children living in their birth families (Van den Dries *et al.*, 2009). However, within the fostered children, rates of disorganization were higher than in controls (36% vs 15%). Both early- and late-placed children showed more disorganized attachments, probably reflecting their experiences of neglect and maltreatment early in life. Nonetheless, these rates show impressive improvements in comparison with institutionalized children, who in the same meta-analysis had rates of disorganized attachment between 66% and 93%.

Among adolescents, Joseph *et al.* (2014) directly compared attachment patterns to biological parents and foster carers within the same individuals using the Child Attachment Interview. While attachment insecurity to biological parents was almost the rule (90% to birth mothers and 100% to birth fathers), there was a high rate of recovery seen in foster care, with nearly half achieving security (46% to foster mothers and 49% to foster fathers)—rates similar to comparison children living in birth families. Factors associated with higher rates of security were longer duration in placement and warmer observed parenting style from foster carers.

Oosterman *et al.* (2010) found that foster children who were securely attached to their carers showed better physiological regulation of emotions during stress; in contrast, disorganized children did worst. In the Joseph *et al.* (2014) study, attachment security was associated with lower levels of emotional and behavioral problems, fewer psychiatric diagnoses, and less self-reported delinquency in both fostered and nonfostered adolescents.

These findings and the meta-analysis comparing separate fostered and nonfostered groups both counter the notion that because of their abusive past experiences lasting several years, late-placed foster children would have developed generalized internal working models that prevented them from forming trusting relationships with adults who care for them. On the contrary, many children who are placed after several years of abuse nonetheless show ability to recover in this aspect of their development.

Psychopathology

The ONS survey found that almost half of children in foster care had a mental health disorder, 45%, compared to 10% of the general population; all disorders were more frequent. Of course, these high rates are probably not only due to the children having experienced neglect and maltreatment; the genetic background of children taken into care will also predispose to high rates of psychopathology and the disruption from their parents and changes of carer may further increase rates of disorder.

Factors influencing successful foster placement

Sinclair *et al.* (2004) followed nearly 600 fostered children longitudinally and used two measures of placement success or failure, the judgments of carers and social workers, and placement breakdown. Five groups of factors were significant. First, within the child, success was more likely if the child wanted to be in the placement, if the child had attractive characteristics, and had few emotional and behavioral problems. Second, in the carers, success was more likely in those who were rated highly by the social workers for their parenting qualities, were "child oriented" on a questionnaire, and had experienced few allegations of abusive practices and few previous disruptions of children in their care. These factors remained important after taking into account child characteristics. Third, it was important how well the carers and the children "clicked," how well each felt they fitted together. Fourth, placements were more likely to be successful where children were happy at school and where their carers said they had been able to encourage them over school; contact with an educational psychologist was strongly associated with an absence of breakdown (again after taking other factors into account). Finally, where there was strong evidence of prior abuse and no birth family member was forbidden contact, breakdown was three times more likely than if it was forbidden.

These detailed findings have been largely confirmed in a meta-analyses and systematic reviews, which find placement breakdown is predominantly related to child behavior problems,

but also is increased by older age at placement, a history of residential care, and more previous placements (Oosterman *et al.*, 2007; Day *et al.* 2013). Investigating the role of externalizing behavior in placement disruption, Fisher *et al.* (2011) used the parent daily report (PDR) telephone interview of antisocial child behaviors to monitor foster placements prospectively for a year. Children displaying fewer than five behaviors a day were at low risk of disruption, but after that each additional behavior increased the probability of disruption by 10%. Using a measure such as the PDR could help detect likely disruptions early on and hopefully lead to interventions to make them less likely.

Kinship care is not protective against placement breakdown, perhaps because of a lack of training and information on the part of kinship caregivers, and perhaps because some of the same factors that led to the biological parents being unable to cope with their children are present in the relatives who take over their care (Terling-Watt, 2001).

Assessment

Introduction

While children in residential or foster care may have had social work assessments, many will not have had a thorough mental health evaluation. It is helpful for the clinician to keep in mind the kind of information set out; thus, for example, as well as suffering abuse at the hands of their birth parents, children may have suffered further bullying or abuse while in care; intellectual levels may be low, rates of psychopathology are likely to be high. It is helpful to have a social worker who knows the child well attend the assessment, along with the foster carers. Although referrers may attribute many of the child's difficulties to insecure attachment or attachment disorders, the clinician should not overlook the presence of conventionally understood disorders.

Taking the history

It is important to ascertain as much detail as possible about the birth parents. Criminality, alcoholism, drug dependence, and other mental health disorders have a heritable component which may help understand the child presentation. Alcohol and substance misuse during pregnancy may have impaired the child's brain development. The intellectual level of the birth parents will also be important; enquiry should be made of the highest level of attainment and whether they appeared to have suffered from intellectual disability.

A careful chronology should be built up of the salient events in the child's life, obviously paying particular attention to the nature of neglect or maltreatment. What factors led the parents to be unable to care properly for the child? Were a series of stepparents involved, what changes of parent figure took place including the number of times the child has come into foster care? What medical conditions does the child have, have they been adequately treated? How is the child doing at school, do

they need much extra help firstly for academic matters and secondly for their behavior? What are their grades, what are the prospects for getting any examination qualifications? Are they being bullied or racially harassed? What is the quality of their friendships, are their friends well adjusted or antisocial?

Turning to the current care arrangements, what is the reaction of the foster carers or residential care staff to the child, why did any previous placements break down? What is the current quality of care? What strategies do the foster carers or residential staff deploy when faced by challenging behavior from the child? What are their feelings toward the child, is there any warmth, what strengths do they see in the child? Will the child come to them to talk about emotional difficulties; will the child give and receive affection? How well can the carers support the child's education, and do they enforce homework?

With respect to the birth family, what kind of contact is occurring; for example, none, letter only, regular visits? Are there any legal orders prohibiting contact, does the child find a way round these through, for example, the Internet or Facebook? What happens during visits; is the child disturbed and upset afterwards? How often do they see their siblings, are they in different placements? How are the birth parents explaining to the child why they are now living at home; for example, are they making unrealistic promises about the child's return? Are the birth parents receiving support and training to improve the quality of their parenting, what are the criteria that would enable the child to return to the birth family? If this is impossible, is the long-term plan for adoption or long-term foster care? If the latter, the clinician will need to judge whether the current foster carers are up to the task of looking after the child, often not an easy task if the child is challenging. Is specialist foster care necessary, and if no such facilities are available, is residential care planned?

Systematic enquiry should ask about all the usual forms of psychopathology. Various forms of neurodevelopmental disorder and symptom clusters that do not quite fit textbook descriptions are quite often seen (Rutter & Sonuga-Barke, 2010), as is poor emotional regulation, with some children taking a long time (sometimes hours) to calm down from angry episodes. Some children will show indiscriminate friendliness. Among teenagers, drug misuse and sexual promiscuity are not uncommon, especially in residential homes that cannot prevent the young people going out at night; sexual abuse of girls by organized rings of men (sometimes in the institution) is not unknown.

Examination and investigations

Observation of the interaction between the foster carers and the child should assess the quality of care given. Is there good sensitivity to the children's needs and interest in their activity and point of view, is there to-and-fro mutuality, are the children acknowledged and praised for good behavior? Or are they dismissed and only talked about in negative terms?

Physical examination should include the nervous system and the presence of any dysmorphic features, for example,

those seen in fetal alcohol syndrome. Height, weight, and head circumference should all be plotted as impaired growth is common; after a period of foster care, there may be catch up and this needs to be documented both for the child's benefit and sometimes to provide evidence for court. If the mental health professional does not have the skills to do the physical examination, they must ensure that a pediatrician carries it out.

Mental health state examination, as well as covering difficulties, should enquire about what the children enjoy doing and their aspirations. Their views and feelings toward their birth parents and foster parents should be ascertained. The former may be realistic, but may be either over-idealized or sometimes birth parents are demonized. Traumatic symptomatology in relation to abuse should be asked about; as with symptoms of depression and anxiety, it may be the first time they have been properly explored. Asking the child for their three wishes is often revealing.

A psychometric evaluation of intellectual ability is usually illuminating, and is mandatory if school performance is below average. Short forms of standardized tests of intelligence and reading can be completed in under an hour (see Chapter 34). If the history and mental state examination had revealed symptoms suggestive of a disorder, domain-specific questionnaires are helpful diagnostically and for monitoring progress.

Formulation and treatment planning

Formulation should follow the structure of any mental health assessment (see Chapter 32). The allure of rare disorders in maltreated children should be avoided; the American Professional Society on the Abuse of Children (APSAC) specifically advises "Although more common diagnoses, such as ADHD, conduct disorder, PTSD, or adjustment disorder, may be less exciting, they should be considered as *first line diagnoses* before contemplating any rare condition, such as Reactive Attachment Disorder or an unspecified attachment disorder" (Chaffin *et al.*, 2006). These cautions are advised since many children in care have had treatable conditions missed but often have had years of counselling therapies not indicated for their disorders. This is not to say that insecure attachment patterns should not be recognized, nor on the rare occasions when present (see Chapter 58), attachment disorders should not be diagnosed. However, the best treatment for these is not an attachment therapy like holding (Chaffin *et al.*, 2006) but prolonged sensitive care from a parent-like caregiver (see Chapter 6) supported by intervention.

In practical terms, it is important to explain the diagnosis and treatment to the social worker who is taking legal responsibility on behalf of the relevant authority; if changes of placement occur, the information should travel with the child. A meeting with the child's school is often fruitful; advice can be given on behavioral management in the school setting as well as the findings from psychometric testing and recommended intervention.

If the foster care quality is insufficient to meet the needs of the child, it is helpful to apply similar evaluation procedures as

in birth families: (1) carrying out an assessment of the carers' current functioning; (2) specifying operationally defined targets for change; (3) implementing an evidence-based intervention; and (4) objectively measuring progress over time, including evaluation of the carers' willingness to engage and cooperate with the intervention and the extent to which targets were achieved.

Intervention

Individual-level work

General principles

For children in residential and foster care, individual clinical work should be carried out using the same principles as for any child with mental health problems. Treatment should consist of the usual evidence-based psychological and pharmacological interventions. Likewise, in the educational domain, a specific educational plan should be drawn up in conjunction with the school authorities and educational psychologists and monitored for its effectiveness. Individual counseling should be offered to help the children make sense of their predicament and, where possible, come to terms with the possible doubt about with whom they will live in future; however, counseling and psychodynamic or creative art therapies are not evidence-based treatments for substantive mental health disorders or attachment problems. Helping residential workers and foster carers learn good management techniques should reduce the rate of prescription of antipsychotic medication for aggressive behavior, which should not be used routinely for severe behavior problems; a wide survey in the United States found that 12% of fostered children were being prescribed antipsychotics, half of whom were receiving two different medications (Rubin, 2012).

Managing contact with birth parents

The degree of contact with the birth parents will need to be managed; in high-risk cases, it will need to be supervised. Contrary to some received notions that contact with birth parents necessarily impedes children making secure attachments to their foster carers, the study of Joseph *et al.* (2014) found it had no effect. Indeed, a large study by McWey *et al.* (2010) found lower levels of conduct problems and depression in children who had frequent contact with their birth parents compared with none, but allowing contact is likely to have been confounded with fewer problems in the first place. Common problems reported by carers include unreliability of birth parents, the impact on children of rejecting parental behavior, and the propensity of parents to try to undermine the carers' discipline (Farmer *et al.*, 2004; Sinclair *et al.*, 2004). During episodes of foster care where there is the prospect of reunion, work with the birth parents should be happening to improve their capacity to care and increase the probability that the child may safely be returned home; unfortunately, this often does not occur.

Interventions to improve residential care

Improving cognitive development

Intervention efforts in institutions have been quite successful; in a meta-analysis, the effect size was large, $d = 0.84$ (Bakermans-Kranenburg *et al.*, 2008). This may point to the extremely disadvantageous rearing environment of institutional settings, and to children's plasticity to overcome their cognitive delays. The timing of the intervention made a difference: those starting before the child's first birthday were significantly more effective ($d = 1.03$) than interventions starting later ($d = 0.58$). Similar effects have been found for children's physical growth (Van IJzendoorn & Juffer, 2007), school achievement, and attachment security (Van IJzendoorn & Juffer, 2006; Van den Dries, *et al.*, 2009). The findings suggest a linear effect, with decreasing effects with children's increasing age at the start of the intervention, and again underline the detrimental effects of structural neglect in the first year of life.

Improving social development

The St-Petersburg-USA Orphanage Research Team (2008) initiated an intervention program to improve the social-emotional relationship experience of Russian children from birth to 4 years. It consisted of staff training (emphasizing sensitive, responsive, and developmentally appropriate interactions) and structural changes (assigning two primary caregivers to lower age and disability groups, terminating transitions of children to new wards, establishing a "Family Hour" for primary caregivers to be with their children). These interventions led to a significant change in the social and emotional behavior of children without and with disabilities, although the latter group needed longer exposure. Specifically, the intervention improved the caregiver-child relationship during free-play with better quality of play, more positive affect, and more positive reciprocal engagement. The rate of attachment disorganization was lower after the intervention (62%) compared to a training-only and no-treatment control orphanages (86% and 85%, respectively).

Interventions to improve foster care

Interventions for infants and young children

Interventions in foster families should support carers' sensitivity and enhance children's attachment security (Juffer *et al.*, 2008a, b), and reduce their antisocial behavior (Leve *et al.*, 2012). A meta-analysis of interventions including foster/adoptive families showed that increasing parental sensitivity led to enhanced attachment security (Bakermans-Kranenburg *et al.*, 2003). The most successful used video interaction feedback, whereby the carer watches videotapes of themselves with the child and is taught to notice the child's reaction to their sensitive overtures and to increase these. The Video-feedback to Promote Positive Parenting-Sensitive Discipline program (VIPP-SD, Juffer *et al.*, 2008a, b) is based on attachment and social learning theory and has been successfully tested with RCTs in maltreating families, adoptive families, and families with externalizing children. There are a number of interventions developed specifically for

foster carers, for example, the Attachment and Biobehavioral Catch-up program (Dozier *et al.*, 2008; see Chapter 6). An RCT showed that as well as enhancing child attachment security, the intervention improved diurnal cortisol production, executive functioning, and emotional regulation (see Chapter 6). The New Orleans intervention is specifically for maltreated children in foster care and works on similar principles.

Starting from a social learning standpoint, Multidimensional Treatment Foster Care (MTFC), originally developed with adolescents, was adapted for younger children. An RCT showed that compared to usual foster care, there were fewer placement disruptions (Fisher *et al.*, 2005), less caregiver stress (Fisher & Stoolmiller, 2008), more securely attached infants (Fisher & Kim, 2007), and more normal cortisol secretion (Fisher & Stoolmiller, 2008) but no evidence has been published that it improves child mental health or behavior. A further trial failed to find any reduction in placement disruptions compared to usual foster care (Fisher *et al.*, 2011).

Interventions for older children

The RCT by Briskman *et al.* (2013) of the Fostering Changes group-based program showed it improved both disruptive behavior and attachment security as rated by carers. This program has now been disseminated to all 152 local authorities in England. A less intensive form of MTFC proved effective in reducing behavior problems by a smaller effect size ($d = 0.26$; Chamberlain *et al.*, 2008). There have also been some less successful trials in middle childhood; thus, the adaptation of the Incredible Years parenting program for foster carers led to no improvement in externalizing behaviors but an improvement in parenting practices (Linares *et al.*, 2006; Bywater *et al.*, 2011). In summary, choosing programs that are specifically designed for foster children and that promote sensitive caregiving, an understanding of the child's predicament and firm limits seem to be most effective.

In adolescence, the best known foster program is MTFC. However, the original trial compared MTFC to incarceration, when it proved effective (Chamberlain & Reid, 1998). A small Swedish replication study showed positive effects in comparison to foster or residential care (Westermarck *et al.*, 2010), but a second Swedish trial comparing MTFC with mainly residential care got no effects on child symptoms, but reduced placement disruption (Hansson & Olsson, 2012). However, a trial in England comparing MTFC with a mixture of foster care and residential care failed to show any effects (Green *et al.*, 2014). In summary, there are encouraging new programs to support foster carers that are often effective in improving attachment security, neurophysiological adaptation, and behavioral adjustment.

Conclusions

Much has been learned in recent years about the development of infants raised in institutions and of older children in residential

care. For infants, the evidence clearly points to a very harmful effect of psychosocial deprivation in the first 6 months of life, with fewer effects after that. On the positive side, institutions can be made less depriving, but in most comparisons young children raised in an adoptive or foster care fare better on a wide range of outcomes. Likewise, residential care for older children may bring a different set of harms, including greater risk of sexual and physical abuse and violence than in foster care. While close relationships with people who care for children are the “golden thread” in their lives, the mental health professional must recognize symptoms and disorders when they are present and instigate appropriate treatment, also promoting the children’s strengths.

CHAPTER 22

Adoption

Nancy J. Cohen^{1,2} and Fataneh Farnia^{1,2}

¹Department of Psychiatry, University of Toronto, Ontario, Canada

²Hincks-Dellcrest Centre, Gail Appel Institute, Toronto, Ontario, Canada

This chapter provides a review of contemporary trends in adoption, including diverse alternatives for those who want to adopt. The chapter proceeds to discuss outcomes of both domestic and intercountry adoptions and to consider issues related to selection, assessment, preparation, and support of families who adopt.

Contemporary trends in adoptive family formation

Decreases in domestic and intercountry adoption

Adoption statistics indicate a decrease in both domestic and intercountry adoptions worldwide. This trend in domestic adoption in developed countries is related to a decrease in available infants, preference for children without special needs and an increase in kinship adoption, adoption by a step-parent, and the accessibility of *in vitro* fertilization and other assisted reproductive technologies (United Nations, 2009). Other factors include politicized issues such as struggling to find an ethnic match and delays due to legal complications (Barn & Kirton, 2012). The decline also may be explained by the decrease in unplanned pregnancies and changing practices surrounding single parenthood.

Since 2007, intercountry adoption from major sending countries declined, while efforts were made to increase domestic adoption. For instance, Guatemala, Vietnam, and Cambodia have suspended their international adoption programs. In China, Russia, and Korea, the number of children available for intercountry adoption has dropped significantly. In 2011, Ethiopia reduced intercountry adoption by 90% (Selman, 2009). Some of the sending countries periodically place a moratorium on intercountry adoption because of concerns regarding unethical practices such as corruption, adoption fraud, bribery, child abduction and trafficking, and irregularities in the adoption process that are inconsistent with the Hague Convention

for Protection of Children and Cooperating in Respect of Intercountry Adoption (2006).

In other countries, political and economic conditions precluded establishment of an adequate social welfare structure and provision of quality foster care and adoption. There is now increasing awareness of the detrimental effects of institutionalization on children and how caregivers' skills and, in turn, children's lives, can be improved (McCall, 2011; see Chapter 58). There has also been a push toward deinstitutionalization, improved social service delivery systems, and emphasis on reunification with birth families, placement in foster care, and adoption (Nedelcu & Groza, 2012).

Further, whereas in the past, children were adopted following natural disasters, local authorities have shifted from sending these children abroad in favor of local solutions. In this way, children are not doubly traumatized by the disaster that made them orphans and a rapid transition to an unfamiliar environment.

A variety of approaches have increased domestic adoptions. Korea provides monthly allowances and health benefits for children adopted domestically, and removed restrictions on prospective parents' qualifications such as age and single parenthood (Lee, 2007; Ministry of Health & Welfare, 2011). Russia removed stringent requirements for housing and income level (Moe, 2007). Immediately following Russia's ban on adoptions from the United States, the government facilitated domestic adoption (The Moscow Times, 2013). Ethiopia provides similar social (Buckner International, 2013) and legal (Ethiopian, 2013) support for domestic adoption.

In China, the number of orphans has increased 24% since 2005 (Shang, 2011). More than 80% of these orphans do not live in government institutions, are not legally adopted and have limited access to resources (Shang, 2008). Nevertheless, the government has maintained restrictions on domestic adoption and added hurdles for international prospective parents' qualifications (i.e., heterosexual married couples, willingness to adopt

children with special needs). Moreover, wait times are longer and procedures more costly.

In major receiving countries (e.g., the United States, United Kingdom, Canada, Australia), there has been a movement to increase domestic adoption. With fewer infants available for domestic adoption, prospective parents must consider adopting “hard to place” or “special needs” children, such as older children, sibling groups, and children with developmental, educational, social-emotional, or medical needs (Henry & Pollack, 2009; Denby *et al.*, 2010). Factors contributing to acceptance of children with a disability include access to health insurance, a positive experience with an individual with a specific syndrome, and religious beliefs (Lindh *et al.*, 2007).

In the United States, foster care special needs children can be adopted through subsidized public programs (Dalberth *et al.*, 2005, National Council for Adoption, 2012). The Adoption Council of Canada (2013) expanded the federal adoption tax to support families who adopt domestically from the foster care system. Research has shown that children who are subsidy eligible are more likely to be adopted (Buckles, 2013).

Alternatives for individuals and families who want to adopt

Open adoption

A few decades ago, information on birth parents was kept sealed. A shift toward openness has now become the norm. A child’s adoptive status cannot be kept secret from older children adopted from institutions or foster care, or from children adopted through international/interracial adoption. In domestic adoptions, children usually are aware of their adoptive status and often have some contact with their birth parents. Openness became more possible once birth mothers could choose conditions for adoption. A continuum of openness ranges from keeping identifying information secret to ongoing contact among members of the adoption triad.

Open adoption leads to greater satisfaction (Siegel & Smith, 2012). Birth parents’ uncertainty about their child’s well-being is reduced, and adoptive parents can obtain important historical information. Further, open adoption helps children to develop a sense of belonging (Grotevant *et al.*, 2011; Child Welfare Information Gateway, 2013). Nevertheless, openness requires commitment and mutual respect from adoptive and birth parents. The best outcomes ensue when adoptive parents demonstrate sensitivity toward the child and birth parent(s) and help the child integrate past and present experiences (Neil, 2003). Openness agreements can vary among families. Because the agreement is not legally enforceable, adoptive families can use discretion to maintain children’s interests. A higher level of satisfaction with contact predicts adoptees’ social-emotional adjustment, especially a lower rate of externalizing behaviors (Von Korff *et al.*, 2006; Grotevant *et al.*, 2011). When disagreements among members of the triad arise, it is essential that they obtain help from trusted adoption workers or family therapists.

Foster care to adoption

Many children are placed in foster care due to maltreatment and neglect (Winokur *et al.*, 2009; Munro & Manful, 2012). Once in foster care, children are unlikely to be reunited with their birth families (Farmer *et al.*, 2011; Wade *et al.*, 2011). In the United States, 54% of children are adopted by foster parents (US Department of Health and Human Services, 2012). This reduces time to permanency, ends uncertainty (Howard & Smith, 2003), and creates connectedness to permanent caregivers (Triseliotis, 2003) while helping children and youth to sustain contact with their birth families (Vandivere *et al.*, 2009). Contact improves a sense of hereditary belonging and identity with the biological family (Grotevant *et al.*, 2011).

Kinship care

Kinship care is another arrangement for children who are victims of maltreatment or whose parent(s) are incarcerated or deceased (Denby, 2012). This is a more stable placement than foster care, residential centers, or group homes (Hunt *et al.*, 2008). It minimizes trauma from parental separation and provides a sense of belonging (Rubin *et al.*, 2008; Winokur *et al.*, 2009). Kinship care also poses challenges. Children in kinship care are often placed with grandparents, who may experience feelings of loss, guilt, and anger over what they believe is their contribution to the birth parent(s)’ abuse or neglect (Kelley *et al.*, 2011). Grandparents are likely to be less educated, unemployed, ill (Cuddeback, 2004; Hairston, 2007), and minimally aware of support services (Fechter-Leggett & O’Brien, 2010). Supporting kinship caregivers reduces stressors that affect permanency of the care (Denby, 2011).

Transracial adoption

The longstanding controversy over transracial adoption remains salient (Blackstock, 2003; Griffith & Bergeron, 2006). In certain jurisdictions, it is highly politicized when it comes to the domestic adoption of Black or Indigenous children by White parents. While child welfare policy identifies within-race adoption as optimal, it may take longer to find a matching family (Brooks *et al.*, 1999; Adamec & Miller, 2007; Barn & Kirton, 2012). Some adoption experts believe that children available for adoption should be matched with families with at least one parent of the same race or ethnicity as the child. Prospective parents who intend to adopt interracially need training on a child’s cultural, racial, religious, ethnic and linguistic background. To achieve positive outcomes, at a minimum, some of the child’s heritage and culture must be integrated into family life (Simon, 1996).

Ethnic identity development also varies according to children’s age and development (Lee, 2003). Because transracially adopted preadolescents tend to identify with their birth culture, it is important to place them in families sensitive to their cultural heritage (Evan B. Donaldson Institute, 2008).

In general, transracial adoption does not result in psychological problems or social adjustment issues in children. Seventy to eighty percent of transracial adoptees have few serious

behavioral and emotional problems, similar to same-race adopted and nonadopted children (Lindblad *et al.*, 2003). However, transracially adopted children and their families face challenges including social discrimination. For example, parents who adopted children from Asia and Latin America reported more discrimination than those who adopted from Europe. Discrimination was associated with greater family stress and more child behavior problems (Lee *et al.*, 2010). Adoptive parents need to be aware of the social and emotional issues that they and their children may face. When parents facilitate their children's comfort with their ethnic identities, the children will have better psychological adjustment, higher self-esteem, greater ethnic pride, and less distress (Mohanty *et al.*, 2007; Johnston *et al.*, 2007).

Assistive reproductive technologies (ART): *in vitro* fertilization, intracytoplasmic sperm injection, donor insemination

ARTs have resulted in the birth of more than 4.3 million children worldwide (ESHRE, 2010) through intracytoplasmic sperm injection (ICSI), *in vitro* fertilization (IVF), and frozen embryo implantation. Where IVF is used, couples have to make ethical decisions, including the options of having their unused embryos cryopreserved and stored or destroyed, donating them for medical research, or putting them up for adoption by others.

The use of ARTs has been the subject of medical, legal, and ethical controversies. Some medical concerns are linked to the risk of pregnancy problems for mothers (Wen *et al.*, 2004) and their babies (Jauniaux, 2012) due to multiple gestations resulting from fertility-enhancing drugs taken before IVF or alternative insemination. Prospective mothers and women donating oocytes who undergo an IVF procedure must be informed of the medical risks associated with this procedure and provide informed consent (Brezina & Zhao, 2012).

Another ethical issue arises around the preimplantation genetic diagnosis (PGD) or screening (PGS) tests, used mainly to diagnose or screen specific genetic conditions or chromosomal anomalies. Since these procedures have become more affordable, an ethical concern is that parents not experiencing infertility may use the tests to create so-called "designer babies" by choosing nontherapeutic physical attributes such as eye color, skin tone, and sex of the baby (Calpern, 2007).

A further ethical issue arises for parents who adopt an embryo or receive a donor gamete. The adoptive parents often grieve losses with regard to infertility and the ability to pass on their genes to create a child genetically related to both. A donor's loss of a potential genetic child may also lead to grief. Frozen embryo donors must make a stressful decision over the future of their frozen embryos, their virtual child (DeLacey, 2005). Almost half of those who considered donating embryos for adoption felt an ongoing sense of responsibility for the well-being of their offspring, and concerns about the quality of adoptive parent caregiving (McMahon & Saunders, 2009).

While adoption openness benefits members of the adoption triad, the practice in ART has been donor anonymity. A review

of studies on donor insemination concluded that only 1–30% of parents intended to tell their children about their genetic origins (Brewaeys, 2001). The reasons for this include social preference for biological parenthood, lack of awareness about the importance of openness, and fear of rejection by the child. However, parents are advised to disclose early on since lack of information about one's origin and genetic ties may negatively affect a person's health and well-being (Paul & Berger, 2007; Cushing, 2010).

In adolescence and young adulthood, the impact of donor anonymity and secrecy about genetic origin is described as a sense of isolation, disconnection, grief and loss, confusion, struggle with identity formation, and anger (Shanner, 2003; Marquardt *et al.*, 2010). These feelings may damage family relationships and place these individuals at risk for adjustment difficulties (Marquardt *et al.*, 2010; Golombok *et al.*, 2013). Therefore, as with adoptive families, it is important for parents to find age-appropriate means to include the truth about their child's genetic origins as early as possible. In some cases it also may be possible to encourage a relationship with the child's biological parent(s).

A higher rate of disclosure is reported among single mothers and lesbian couples (Jadva *et al.*, 2009; Beeson *et al.*, 2011). The situation is changing, however, and increasingly more parents of donor offspring are willing to disclose to their children their donor conceived status. Moreover, the policy of donor anonymity is being rethought, systems of open-identity donation are in place in some countries and the donor offspring are entitled to identifying information about their donors when they turn 18 (HFEA, 2009).

Another concern about donor anonymity is the number and identity of children conceived using the same donor. Laws regulating sperm donation address this issue. However, there is great variability in the number of children allowed to be born from each donor in different jurisdictions. The numbers range from 3 offspring in Hong Kong to 25 in Canada and the Netherlands. The Donor-Sibling Registry is a worldwide organization that helps individuals conceived by any ART practice and parents of donor offspring to find donors and genetic half siblings (Freeman *et al.*, 2009).

Gay and lesbian adoption

Single women have been able to adopt a child for some time, but adoption has not been so readily accepted for gay, lesbian, bisexual, and transgendered (GLBT) individuals or couples. While gay and lesbian parenting has become more common, little is known about parenting by bisexual and transgendered individuals and couples.

Gay and lesbian parenting began with consideration of the rights of parents coming out of a heterosexual marriage (Goldberg & Gianino, 2011). A new generation of gay and lesbian individuals assumes that parenting is a right and plan to become parents (Lev & Sennott, 2013). Some individuals have an

agreement with a known partner to conceive a child. Others use ART or a surrogate or adopt a child (Berkowitz, 2013). Both legal and emotional issues inform the choice of the means for having a child. When one individual gives birth or adopts, the partner can adopt as coparent. This places the coparent at a disadvantage regarding legal status that can create difficulties if the couple separate. Where gay and lesbian marriage has become legal, the parental rights of both parents are respected, thus alleviating both legal and emotional concerns. Also, physiological changes in the parent giving birth, and the child's possible preferential reaction, can disturb the sense of equality. Some lesbian couples resolve this issue by taking turns going through a pregnancy and birth. Longitudinal studies of adolescents and adults indicate that it is not parents' sexual orientation but family process variables, important in all families, that are critical (Mellish *et al.*, 2013). This includes low parenting stress and qualities of the couple's relationship with one another and with their children (Averett *et al.*, 2009). Contextual factors, including acceptance of extended family, neighbors, schools, and religious institutions are related to children's outcomes. Children's overall adjustment, including gender role behavior, is not adversely affected (Goldberg *et al.*, 2011; Patterson & Wainright, 2011). Moreover, children of gay and lesbian parents do not differ in their cognitive ability, school performance, or social-emotional health. Some individuals had problems with trust in adulthood primarily related to their parents' coming out unexpectedly and experiences of being teased and bullied (Goldberg, 2007).

In fact, gay and lesbian households may have low levels of parenting stress as adopting parents tend to be well educated and professionally and financially secure (Farr *et al.*, 2010). Longitudinal studies also suggest that youth of lesbian and gay parents are more tolerant and have more flexible ideas about gender and sexuality (Goldberg, 2007). Moreover, being raised without a father from infancy does not seem to have negative consequences for social and emotional development for children (MacCallum & Golombok, 2004). Similar findings about motherless children are not yet available. Although there is little systematic study of lesbian and gay couples in open adoption arrangements, these couples may be more accepting of open adoption because they appreciate the concept of openness generally and more likely to view nonfamily related individuals as kin (Goldberg *et al.*, 2010).

Lesbian and gay couples are more open to transracial and special needs adoptions (Goldberg & Gianino, 2011) and have been solicited for adoption of these children (Downing *et al.*, 2009). This greater openness may result from their own experiences of being unaccepted or marginalized or having to wait longer than heterosexual couples for private domestic adoptions where a birth mother chooses the adoptive parents (Farr & Patterson, 2009; Ausbrooks & Russell, 2011).

Acceptance of gay and lesbian adoption is greater among private secular adoption agencies, and some faith-affiliated agencies (Matthews & Cramer, 2006; Brodzinsky, 2011). Training of adoption workers to facilitate such adoptions and to

provide ongoing support is often limited as is having GLBT staff workers (Goldberg & Gianino, 2011; Mallon, 2011). Taken together, research concludes that decisions about children's and adolescents' placement into adoptive homes should not focus on parental sexual orientation.

It is important to discuss implications of the prospective parents' sexuality for their children within the extended family, at school, and in the community. The parents also will need to explore children's views of their parents' sexual orientation and their responses to potential reactions from teachers and peers. Clinicians can play an important role in understanding and supporting life course events and transitions for lesbian and gay individuals and couples and their adopted children.

Opening the birth records: search for birth parents (including ART donors)

Sealing birth and adoption records was meant to provide stability to adoptive families and a chance for a new start to birth parents. While adopted children have the highest stake, their rights to biological information, cultural heritage, and medical history were not considered. Research has shown that mothers who relinquish a child may experience persisting mental health issues (Novac *et al.*, 2006). Legislative changes now allow more openness in adoption and take into account the constitutional rights of both adoptees and birth parents by facilitating search and contact between these parties.

Pursuit of birth parents or gamete donors often becomes important once adopted children reach adolescence or adulthood when unresolved psychological and identity issues come to the fore (Curtis & Pearson, 2010) or at a life cycle transition (Campbell *et al.*, 1991). Gender, self-esteem, degree of openness in adoption, age at adoption, and quality of the adoption experience distinguish searchers from nonsearchers (Howe & Feast, 2000). The search tends to be stimulated by the desire to know the birth parent's history and motivation for placing a child for adoption or donating and to seek health information. For birth mothers/parents, the search and reunion is motivated by assuring their children's well-being, how they are being parented, letting them know that they were loved, and explaining the reasons they were given up (Petta & Steed, 2005).

Adoptees' search and hope for reunification often focuses on the birth mother (Trinder *et al.*, 2004) although increasing numbers seek contact with their birth fathers (Clapton, 2003; Passmore & Chipuer, 2009). While some adoptive parents believe that this is their children's choice and right to know about their genetic origin, others are reluctant to have their child form an attachment relationship with a birth parent or gamete donor (Wallbank, 2004). Parents are more open to the possibility of their children developing attachment relationship with their donor siblings (Freeman *et al.*, 2009).

Reunions have positive outcomes for adopted children and birth parents (Lifton, 1994; Cavoukian, 2005). However,

unfulfilled hopes and unrealistic expectations of the reunion may negatively impact the emotional stability and security of both parties (Howe & Feast, 2001; Kelly, 2005; Feeney *et al.*, 2007).

While the majority of adoptive parents reported satisfaction with contact (Siegel & Smith, 2012), children's search for their birth parents may be the most emotionally loaded moment in adoptive parents' lives. They may feel that the unexpected, unplanned contact will harm their relationship with their children and their role and identity as parents (MacDonald & McSherry, 2013). Adoptive families who support their children's search and are involved in their reunion decision making are less stressed than those who disapprove of reunions (Silverman *et al.*, 1994). They are likely to remain active members of the adoption triad and establish friendly relationships with the birth family (Howe & Feast, 2000).

Outcomes of adoption

Outcomes of domestic adoption

The positive outcomes for domestically adopted infants have been well documented with respect to aspects of development and attachment security (van IJzendoorn & Juffer, 2006). Because there is a shortage of healthy infants available for adoption, older children and those with other special needs continue to be available for adoption in large numbers. Children who are older at adoption, or have other special needs, initially show more emotional and behavior problems that can make parenting more challenging. With respect to school performance, when compared to nonadopted siblings, adopted children performed better at school but lagged behind current nonadopted peers (van IJzendoorn, & Juffer, 2005). Nevertheless, once adopted, the outcomes for these children are generally positive (Rushton & Dance, 2006; Child Welfare Information Gateway, 2012).

Child, parent, and agency factors contribute to adjustment of children with special needs. Child factors include presence of emotional and behavioral problems, strong attachment to the birth mother, and being a victim of preadoption sexual abuse. Parent factors include being a new parent rather than the child's foster parent, receiving less support from relatives, being more highly educated and having unrealistic expectations of the child (Hussey, 2011). Agency factors include placement through a public rather than private agency and having a less experienced caseworker (Child Welfare Information Gateway, 2012). Accurate information about the child and the child's history, along with support through the preparation and placement process, help parents gain a realistic understanding of their child and the comfort to make a gradual transition to adoptive family life. It is important to keep in mind, however, that these families often move through stages of adjustment in the postadoption period, especially with children with special needs (Pinderhughes, 1996). In this process, families often have to relinquish fantasies of the adjustment process and make accommodations to a child

who tests limits. In doing so, parents' expectations are unmet, creating ambivalence about the adoption. Clinicians can help parents both to discuss and alter their expectations such that expectations and reality become more closely matched.

Outcomes of intercountry adoption

Intercountry adoptees typically lived in institutions prior to adoption and infrequently experienced foster care. Institutional living poses risks for infectious diseases and neurological problems and is associated with lack of adequate cognitive and social stimulation and individualized attention (van IJzendoorn & Juffer, 2006; Miller, 2012). These children tend to be short, weigh less, and have a small head circumference. Catch-up growth and improved health follow adoption, especially for children adopted by or before their first birthday and from relatively less depriving circumstances (van IJzendoorn *et al.*, 2007; Cohen *et al.*, 2008; Bakermans-Kranenburg *et al.*, 2011) compared to those raised in extremely depriving environments over an extended period (Sonuga-Barke *et al.*, 2008). Moreover, children adopted internationally are at risk for early puberty, often accompanied by shortened final height and more social-emotional problems (Teilmann *et al.*, 2006).

Research has shown that postadoption outcomes depend not only on age but also on the quality of institutional care. Children adopted by 1 year of age typically fare best in terms of language, cognitive and social-emotional development (van IJzendoorn & Juffer, 2006; van Londen *et al.*, 2007; Cohen *et al.*, 2008). However, children adopted from extremely depriving institutions after 6 months of age (e.g., in Romania) exhibited problems in language and cognition at 6, 11, and 15 years of age compared to Romanian children adopted younger than 6 months and children adopted within the United Kingdom (Rutter *et al.*, 2010).

Regarding attachment, infants adopted at a relatively early age (i.e., at or before 1 year) (Stams *et al.*, 2002; Pugliese *et al.*, 2010; Cohen & Farnia, 2011a) or raised in institutions that created conditions for forming a secure attachment (Vorria *et al.*, 2006) do not exhibit attachment difficulties. However, children adopted later, who did not experience sensitive and responsive individualized caregiving, often show signs of insecure or disorganized attachment and sometimes indiscriminate approach to strangers (Rutter *et al.*, 2007).

Intercountry adoptees are consistently overrepresented in mental health services, but the sources of emotional and behavioral disturbance may be different from those shown by domestic adoptees (Juffer & van IJzendoorn 2005), possibly as a consequence of preadoption conditions. A parent survey of internationally adopted children aged 4–18 years showed that early institutional rearing was associated with increased rates of attention and social problems, but not internalizing or externalizing problems (Gunnar *et al.*, 2007). Children adopted from Romania into the United Kingdom after the age of 6 months exhibited a unique constellation of symptoms that persisted into adolescence marked by inattentiveness/overactivity, quasi-autism, and disinhibited attachment, which were

qualitatively different from such disorders observed in clinical settings (Kumsta *et al.*, 2011). Parenting stress is one factor related to behavior problems in school-aged internationally adopted children (Gagnon-Oosterwaal *et al.*, 2012).

More subtle behavior traits have been observed in some children adopted relatively early from a less depriving environment. Mothers of infants adopted from China, on average at 1 year of age, consistently rated their daughters as more emotionally reactive than nonadoptive mothers over four time points in their first 2 years postadoption (Cohen & Farnia, 2011b). In older children, Tan (2011) reported that internalizing problems in Chinese adoptees increased from preschool to school years.

Relatively little is known about intercountry adoptees in adulthood. Teilmann *et al.* (2006) found that adult male adoptees were less likely to have intimate relationships, to live with a partner, and to be married but did not differ in educational or professional attainment. In another study, girls adopted from Hong Kong by British parents at approximately 2 years of age were followed into midlife (Feast *et al.*, 2013). These women reported positive outcomes in health, education, occupation, close relationships, and social-emotional functioning.

Selection, preparation, and assessment

Prospective parent(s)' suitability for adoption is based on individual and joint interviews and documentation regarding health and finances and home and neighborhood environment. A history of secure attachment relationships, relationships with one another (for couples) and with extended family, parenting capacity and communicative openness are important parts of the equation. Personal references, including a criminal background check, are also required. In addition, adopting parents are asked about their reasons for pursuing adoption, characteristics of a child they are interested in adopting, and their readiness to adopt (Crea *et al.*, 2007). For families adopting children of a different race or with special needs, attention is paid to flexibility of parent expectations about children who may require additional attention. The adoption process can be especially complex and lengthy for older children who have a history of abuse, parent drug and alcohol use, or rejection by foster parents. Optimally, the process continues after these children join their adoptive family, with periodic visits by an adoption social worker to evaluate and facilitate the progress of family formation (Hanna, 2007). Comprehensive preparation has been related to less frequent use of both general and clinical postadoption services (Wind *et al.* 2007).

Assessment of adopting parents is done by a qualified individual through a publicly funded child welfare system, an international adoption agency, or an independent facilitator such as a lawyer. It is essential to ensure that children will be safe and supports appropriate to their needs provided. Prospective parents also need to know what to expect of the children's behavior and learning abilities (Rushton & Monck, 2009). When available,

adoptive parents need to be informed about genetic or biological factors that may influence children's health and adjustment.

The home study is often accompanied by group meetings with other potential adopters and parents whose adoptions are completed and can provide a realistic view of what to expect. In the case of intercountry adoptions, considerable time is spent talking about the conditions in which children lived, cultural practices that parents may want to continue, and what can be expected of children's health, development, and attachment. In a study of preparedness for intercountry adoption, many families felt minimally prepared for the adoption process and the emotional challenges they might face. Preparation was found to be positively associated with satisfaction with the adoption (Paulsen & Merighi, 2009).

Children also need to be prepared for adoption and encouraged to feel entitled to have permanent parents. Older children are given an age-appropriate explanation of why they will not be living with their birth or foster parents. Creating a life book helps children remember and put the various people and events in their lives into sequence and perspective and understand why their birth parents and/or foster parents could not continue to care for them. It also helps children reframe prior experiences in a realistic, yet positive light. Making children part of this process helps them to explore feelings of loss, anger, and confusion as well as remember positive experiences. For children who do not have such information, as is the case with intercountry adoptees, records of the events on children's birthday and photos of the institution or surrounding environment can be helpful. Adopting parents must understand the importance of this process without prematurely negating children's pasts in order to "move on." Having a life book also may prepare children to engage in classroom activities such as drawing a family tree. Unfortunately, life books are not consistently available (Hanna, 2007).

Postadoption services

Being adopted approximately doubles the chance of having contact with a mental health professional (Keyes *et al.*, 2008; Hussey *et al.*, 2012). This is likely determined by both longstanding effects of preadoption stressors and the tendency of adoptive parents to seek services. Moreover, the need for postadoption clinical services increases over time with changes in children's physical, behavioral, and emotional needs. It is also necessary to keep in mind that parents, particularly mothers who are less emotionally stable prior to adoption, are at risk for postadoption depression in the first year after a child joins the family (Payne *et al.*, 2010; Foli *et al.*, 2012). When this happens, it is important to provide clinical services as quickly as possible.

The increase in children adopted from foster care places expanding demands on postadoption preservation and clinical services for both parents and children. Parents often feel particularly unprepared to manage their child's emotional and behavioral problems (Rushton & Monck, 2009). Issues identified

by families as areas of need include stress reduction, forming realistic expectations, attachment, separation, loss and grief, and child and youth identity formation. Moreover, medical and developmental conditions that require referral to specialized clinics may be present.

Given the varying experiences of adopted children, a one-size-fits-all model of intervention is insufficient. Post-adoption services include ongoing meetings with the case-worker, participation in adoption support groups, clinical interventions, and crisis intervention (Howe, 2006; Wind *et al.*, 2007; Vostanis, 2010). From a survey of families that adopted children with special needs, financial, medical, and dental supports and subsidies also emerged as postadoption service needs (Reilly & Platz, 2004). There are further needs for in-home supports such as respite care. Receiving financial and social work assistance and involvement in informal support groups are associated with higher parenting satisfaction. There is a particular need for support groups for families adopting transracially to address struggles around racial identity (Evan B. Donaldson Adoption Institute 2010; Adkison-Bradley *et al.*, 2012).

Although many families seek clinical services, they often complain that mental health professionals are not “adoption competent” (Riley, 2009). An ongoing theme is the importance of educators and clinicians receiving specialized training related to the adoption family life cycle and mental health issues associated with adoption including loss and grief, identity, the birth family search process, and attachment (Evan B. Donaldson Adoption Institute 2010; Palacios 2012). In addition, families need information regarding the adoption kinship network, and genetic and other biological risks that contribute to adjustment (Palacios, 2009).

A specific concern is that clinicians view difficulties through a lens of family pathology rather than family development. This is especially important because children’s understanding of adoption changes with age. Developmental turning points are most marked in the early school years when children truly understand the meaning of adoption and in adolescence when issues of identity and their reproductive future may cause emotional upset (Brodzinsky, 2011). Thus, it is essential for clinicians not to pathologize what might be part of an expectable adjustment process that includes adoptees’ grief and anger, sensitivity to rejection, and fears about being unlovable, especially if they act out in some way. The importance of parents openly discussing adoption-related issues with their children as they emerge and supporting their child who may grieve is critical (Brodzinsky, 2011). In fact, adolescents who perceived greater communication openness reported more trust in their parents, fewer feelings of alienation, and better family functioning (Kohler *et al.*, 2002).

Promoting a positive attachment relationship is an important step in the adoption process. For instance, a book and video-feedback program directed at increasing maternal sensitive responsiveness was found to improve both maternal sensitive responsiveness and infant competence and attachment

(Juffer *et al.*, 1997). When seen again at 7 years of age, these children showed fewer internalizing behavior problems and more resilience than children who had not received the intervention (Stams *et al.*, 2001). Attachment-based interventions used to help children form a relationship with foster parents might also be applied to adoptive families (see Chapters 6 and 58). Unfortunately, some parents use remedies that lack supporting evidence described on Internet sites for treating children with attachment problems.

In a study of older children, Rushton and Dance (2009) compared two manualized 10-week home-based parenting programs with families whose adopted children showed problems in the first 18 months postplacement. One program took a cognitive behavioral approach and the other an educational approach. Adoptive parents reported a significant reduction in negative parenting techniques (e.g., threats, telling off), but no significant differences in child behavior. Similarly, a survey of adoptive parents showed that postadoption services improved understanding of adoption and the adopted child but had less impact on behavior problems or peer and sibling relations (Dhami *et al.*, 2007). These programs are time limited; in reality, there needs to be longer term programming or options for parents to return for service as their needs change over time. Clearly, more controlled studies of postadoption services are required and their outcomes followed longitudinally. Despite the challenges associated with adopting children with special needs, it is important to emphasize that the majority of adoptive parents report good adoption outcomes.

Adoptive families also pursue nonclinical service options. They seek or organize workshops around specialized topics, establish Internet chat groups, and search for websites to provide support and answers to their concerns. For parents who have adopted internationally, supports often are provided by organizations related to adoptions from a particular country (e.g., Families with Children from China). There also are group initiatives for the children themselves. It would be worthwhile to know the outcomes of participation in these various support groups.

Conclusions and future directions

Adoption continues to play a prominent role in the fabric of family life worldwide. Yet the nature of adoption has changed, and so too the topics for research. For instance, there is still a need to follow intercountry adoptees into adolescence and adulthood. Thus, it is important to understand the outcomes of a wide spectrum of early experiences. More research is also needed on the rights and needs of gay and lesbian individuals and couples and to understand the outcomes for transgendered and bisexual individuals who choose to be parents.

There is greater acceptance of openness in adoption. In the past, this applied primarily to adopted children but now is being considered for both younger and older children born from use of ARTs. There is a growing trend for intercountry adoptees to

seek their birth families or siblings through the Internet and/or visits to their birth country. These continuing shifts in openness invite future research.

Historically, relinquishing a child for adoption was in the hands of the birth mother. More recently, an ethical dilemma has arisen for some infant adoptions when a birth father's agreement for adoption is not sought. In some jurisdictions, a putative father registry has been established to claim paternal rights. While such cases periodically appear in newspapers, empirical findings are sorely lacking.

Finally, it is essential to continue specialized training and evaluation of efforts to ensure the adoption competence of mental health professionals, teachers, social service workers, physicians, and lawyers. Moreover, there is increasing need for therapists who can work with gay, lesbian, bisexual, and transgendered parents and kinship adoptions. An important future goal is to provide a stronger evidence base for all postadoption services.

PART II

Influences on psychopathology

CHAPTER 23

Biology of environmental effects

Michael Rutter and Camilla Azis-Clauson

Institute of Psychiatry, Psychology and Neuroscience, King's College London, UK

Introduction

Throughout the previous five editions of this book, there was much discussion about the importance of experiences in the liability to different forms of psychopathology. However, this edition marks a substantial change in the way that the issues are considered. There is a chapter on the effects of psychosocial stressors and chronic adversities (see Chapter 26) and a separate chapter on resilience (see Chapter 27) in relation to those adversities. Here, however, the focus is exclusively on the biology of environmental effects. This has meant that the range of experiences being considered has widened considerably. Thus, experiences include the effects of treatment and the role of physical hazards of various kinds, as well as psychosocial influences. There is also an extension in the time periods covered, particularly the inclusion of the prenatal developmental period (see Chapter 9), and an extension into adult life. Finally, there is a focus on seeking to provide an understanding of causal pathways and mediating mechanisms. These include the role of epigenetics (concerning the processes involved in gene expression; see Chapter 25) on the hypothalamic-pituitary-adrenal (HPA) axis, and on inflammation, as well as attention to the effects of the dose and timing of experiences. There has been a substantial increase in the knowledge base on all of these, although we emphasize that much remains to be learned. Tottenham and Sheridan (2010) have argued for the importance of considering developmental timing when studying the biology of environmental effects. They noted the value of animal models (see Chapter 12) but also emphasized the need for prospective human studies with multiple data points. Nevertheless, what has been learned has enabled a considerable sharpening of the questions that have to be considered in relation to environmental effects on biology (Rutter, 2012a). We start the chapter by considering prenatal effects and then move on to a range of postnatal experiences.

Prenatal experiences

Maternal drinking of alcohol during pregnancy

In 1973, Jones *et al.* (1973) reported an unusual syndrome of malformations in the offspring of chronic alcoholic mothers. A distinctive set of facial features was evident and it was argued that these reflected damage to the developing brain brought about by exposure of a fetus to high alcohol levels in early pregnancy. Numerous reports in humans confirmed the observation and indicated that this was accompanied by abnormalities in behavioral development (Gray & Henderson, 2006). The causal inference was made more likely by the specific link with the first trimester of pregnancy (Day *et al.*, 1989). It was supported by studies in mice showing that the embryos developed craniofacial malformations closely resembling those seen in the human fetal alcohol syndrome (Sulik *et al.*, 1981). Later mouse studies went on to show strain differences in vulnerability to alcohol (Becker *et al.*, 1996) and reprogramming of genetic networks (Green *et al.*, 2007).

Studies of children exposed *in utero* to alcohol, but adopted or fostered in early infancy, have helped indicate the reality of the prenatal effects—because, despite rearing away, they still showed sequelae (Moe, 2002; Singer *et al.*, 2004). Human studies (Gray & Henderson, 2006) have shown that alcohol exposure in early pregnancy can lead to adverse developmental or psychopathological effects even when the characteristic congenital stigmata were absent. But uncertainty on how to diagnose these more subtle fetal alcohol effects remained. In addition, it was not clear whether the damage mainly reflected very high, but episodic, alcohol exposure (such as brought about through binge drinking), or whether it reflected an overall total “dosage” of alcohol exposure during the key time period. Uncertainty similarly remained on the extent to which the effects extended throughout later periods of the pregnancy and on whether even

low levels of alcohol exposure in early pregnancy can bring about adverse effects of brain development.

Two recent findings are potentially informative regarding fetal alcohol effects on brain development. First, there is the tentative evidence on neural associations. Yang *et al.* (2012) reported that abnormal cortical thickness was associated with disrupted brain development in a clinical study, with the suggestion that cortical thickness might serve as a biomarker for an abnormality in brain development. Somewhat similarly, Lebel *et al.* (2012), in a two-year follow-up study of alcohol-exposed and nonexposed individuals (the former being recruited from a teratology clinic and the latter being volunteers), found that the cortical volume trajectories differed between the two groups. However, as the authors noted, whether this difference reflected very heavy alcohol exposure or other more prolonged dysfunctional experiences during childhood and adolescence was uncertain.

The second finding reported by Lewis *et al.* (2012) was based on using a Mendelian randomization design with the Avon Longitudinal Study (ALSPAC) sample, finding that low to moderate amounts of alcohol exposure during the pregnancy had effects on IQ. It is unknown whether these were a function of effects on the brain. As indicated, there are still important questions to be considered in relation to alcohol exposure in the pregnancy, but what is clear is that there are teratogenic effects from alcohol exposure during the first trimester, with queries as to whether there are any effects later in pregnancy.

Exposure to mother's smoking during pregnancy

Smoking exposure during pregnancy has been shown by animal models to have effects on birth weight (Office of the US Surgeon General, 2006). Human studies, too, are informative on whether the effects are specific to a particular trimester of pregnancy. Lieberman *et al.* (1994) in a study of a cohort of some 11,000 women found that exposure to smoking during the second and third trimesters only, was associated with a doubling of the frequency of small by gestational age births. By contrast, smoking in the first trimester only, or first and second trimester only, gave rise to a frequency that did not differ from that found with nonsmokers. Bernstein *et al.* (2005) confirmed the substantial effect of smoking in the third trimester in leading to a reduction in birth weight but there was no comparison with earlier trimesters. Ordinarily, the effects of stopping smoking during the pregnancy ought to be helpful in inferring causation but interpretation is complicated by the substantial differences between mothers who give up smoking and those who do not (Nordström & Cnattingius, 1994; England *et al.*, 2001).

What is striking in the comparison between the effects of exposure to maternal drinking and exposure to maternal smoking is that, although there are effects on the fetus in both cases, the pattern is quite different. Smoking is not associated with the congenital anomalies found with fetal alcohol exposure and the timing is quite different. Alcohol effects are greatest in the first

trimester and smoking effects are greatest in the last trimester. Suter *et al.* (2013) discussed whether the reduced fetal growth following smoking exposure was a consequence of the genetic changes, but this is a possibility that has still to be systematically investigated.

One of the very few studies to examine the effects of maternal smoking on fetal growth during the pregnancy was undertaken by Jaddoe *et al.* (2007) using the prospective Generation R Study in the Netherlands, with a sample size of some 7000. Fetal ultrasound examinations were undertaken in early, mid, and late pregnancy. The findings showed that the babies of mothers who smoked until they discovered they were pregnant, but then gave up smoking, showed no difference in head circumference growth from the babies of nonsmokers. By contrast, mothers who continued smoking after the pregnancy was known had babies that showed a significant impairment in head growth, as well as impairment in other growth indices, such as abdominal circumference and femur length. These differences still held after adjusting for a range of confounders.

Although findings from natural experiments indicate that exposure to maternal smoking during the pregnancy does not show a significant association with behavioral outcomes, the same evidence also indicates that there is a robust effect in lowering the birth weight (a finding confirmed from animal models). Recent work suggests that the mechanism may lie in epigenetic mechanisms (Knopik *et al.*, 2012; see Chapter 25).

Haghighi *et al.* (2013) used magnetic resonance imaging (MRI) of the brain to compare adolescents who had and who had not been exposed prenatally to their mother's smoking. Those exposed had a slightly smaller amygdala volume. The findings were interpreted as broadly in line with studies in adolescent rats (Kane *et al.*, 2004; Slotkin 2004; Chen *et al.*, 2005).

Prenatal exposure to cocaine

The consequences on the fetal brain of gestational cocaine exposure are much less well documented and understood. One of the practical problems has been the fact that most use of drugs of abuse involves several drugs and isolating the effects of just one (in this case cocaine) is tricky. Nevertheless, such limited evidence as there is suggests that, in some cases, there can be effects on brain structures (Derauf *et al.*, 2009). Their review concluded that clinical evidence suggested that cocaine independently contributed to impairment in brain growth that was prenatal in origin and exhibited an inverse dose-response relationship. Nevertheless, this selective impairment of brain growth occurred in only a subset of infants. Part of this was mediated through an indirect effect of poor maternal nutrition as well as a direct effect of cocaine. Zuckerman *et al.* (1989) concluded that the resulting deficits from cocaine were more subtle than those with alcohol. Their prospective study of infants followed from pregnancy onward concluded that the

use of marijuana or cocaine during pregnancy is associated with impaired fetal growth and that measuring a biological marker of such use is important to demonstrate the association (Zuckerman *et al.*, 1989).

Dow-Edwards (2011) has provided a useful review of how to evaluate animal models studying the effects of prenatal cocaine when applied to the human situation. It is noted that translation from preclinical studies is influenced by the dose of the drug administered, the timing of events in brain development in the animal compared to the human, and the pharmacokinetics of the drug in animals and humans. The review concluded that there is ample evidence for the biological effects of cocaine on cortical and mesolimbic dopamine system development, but the manipulation of the rearing environment can dramatically alter the manifestations of these effects, including function of the mesolimbic dopamine reward system.

Prenatal exposure to depression/anxiety and antidepressant medication

Rather little is known about the facts of prenatal exposure to antidepressants taken by the mother but such evidence as there is suggests that the risks are low. From a practical point of view, clinicians have to balance such risks as there may be from the medication against the risks associated with maternal anxiety or depression. Peña *et al.* (2012) summarized the literature showing that, in humans, the experience of stress during pregnancy is associated with an increase in preterm birth, reduced birth weight, and smaller head circumference. The long-term consequences for offspring have been demonstrated in laboratory studies using rodents. Stress-induced elevations in maternal glucocorticoids have emerged as a primary mechanism of prenatal stress effects, supported by studies in rats in which the effects have been prevented among adrenalectomized females. Peña *et al.* (2012) conducted a study in rats in which restraint stress was brought about by placement in a small cage that prevented vertical and horizontal movement for 1 hour per day from gestational days 14 to 20. The findings showed significant effects on the placenta and the details suggested epigenetic regulation as a likely mediator of effects on the offspring. Lupien *et al.* (2007) in their systematic review, noted that glucocorticoids could cross the blood–brain barrier and that this was likely to be a key feature in effects on the brain of the offspring.

Maternal depression and antidepressants compared

The question of whether maternal antidepressant treatment during pregnancy is better or worse for the offspring than untreated maternal depression constitutes a key question for clinical practice (Steiner, 2012). However, the question should not assume that there is a prenatal effect of either, because depression during pregnancy is a significant risk factor for postpartum depression (Nulman *et al.*, 2012). Nevertheless, animal models suggest that there may well be neurodevelopmental

effects of prenatal antidepressant exposure (Ansorge *et al.*, 2004; Oberlander *et al.*, 2009).

Animal studies have shown the fetal programming of the hypothalamic/pituitary adrenal (HPA) axis function and behavior by synthetic glucocorticoids. It appears that the changes in HPA axis function persist throughout life, indicating some kind of programming effect (Davis *et al.*, 2011). Because the findings go across multiple animal species, and because they derive from randomized experiments, there is every reason to infer a causal effect. In humans, maternal cortisol, as measured through gestation, is associated with a larger right amygdala volume in girls but not in boys. It remains unclear why there is such a definite sex difference but sex differences have been found in many functions (Buss *et al.*, 2012). The findings indicate that there are neural effects of maternal stress hormone levels and not just programming effects on the HPA axis (Sandman *et al.*, 2012).

There are now a number of studies making systematic comparisons between prenatal exposure to maternal stress or depression and prenatal exposure to antidepressants (Nulman *et al.*, 2002; Pedersen *et al.*, 2013). An important study by Weikum *et al.* (2012) similarly focused on the comparison between antidepressants and depression that had not been treated by medication, but differed in using infant speech perception as the outcome measure. The findings suggested that serotonin reuptake inhibitors (SRIs) were associated with an accelerated timing of perceptual attunement. By contrast, maternal depression had the opposite effect in delaying speech perception differences. The findings are important in their reminder that it is not sufficient to compare the same effects of maternal depression and maternal use of antidepressant medication but also to consider that the two may differ in their pattern of effects.

In their useful review, Hanley and Oberlander (2012) summarized three main themes. First, prenatal antidepressant exposure alters central 5HTT levels but the developmental outcomes do not necessarily reflect a main effect due to one causal factor, such as maternal mood, genetics or the drug. Rather, outcomes represent an interplay among psychological, pharmacological, genetic, and social factors relating to the mother and her child. Second, although medication is prescribed during pregnancy with the expectation of optimizing infant health outcomes following associated improved maternal mood, children may continue to be at risk because the treatment may not buffer or protect them from postnatal maternal mood disturbances. Third, there is a context of developmental vulnerability as well as plasticity.

Two further studies complicate the picture. First, Simpson *et al.* (2011) in a study of drug-exposed rat pups found that perinatal drug exposure seemed to affect males more than females and that drug exposure was accompanied by a reduction in callosal connectivity. Both the sex difference and the effects on neural function are different from what is found in humans but the reasons for this remain unclear. Second, Croen *et al.* (2011) reported a human study based on healthcare records, with a

finding that prenatal exposure to antidepressant medication was associated with an approximate doubling of the risk of an autism spectrum disorder in the offspring. The authors point out that the causal inference could have been due to uncontrolled confounding by variables that were not measured and that it was also the case that the fraction of cases of autism spectrum disorder attributable to antidepressants was very low—less than 3%. Further research is obviously indicated but findings do not, as yet, warrant public health action.

Lastly, it is important to note that the rate of maternal depression tends to be increased in the context of poverty and disadvantage. The effects must be considered bearing that in mind.

We conclude that, on the evidence available so far, the risks to the fetus associated with maternal depression outweigh possible risks associated with antidepressant medication. Inevitably, in view of the limited direct evidence, that must be a provisional conclusion but we agree with the various commentators who have all argued that it remains important to treat maternal depression without undue concern for the unknown risks of antidepressant medication. On the other hand, this may be a circumstance in which the use of psychological treatments has much to recommend it.

Prenatal effects of subnutrition/famine

The problem of studying the effect of subnutrition/famine is that, in ordinary circumstances, it is very difficult to separate the effects of the famine from the effects of the characteristics that led to the particular individuals being subnourished. The way around this problem has been to study the effects of famine that applied to the total population. The Dutch famine during the winter of 1944–1945 provided the natural experiment (Stein *et al.*, 1975). Unlike other famines, the Dutch hunger winter struck at a precisely circumscribed time and place and in a society able to document the timing and severity of the nutritional deprivation as well as its effects on fertility and health (Susser *et al.*, 1998). A follow-up of military inductees showed an increased rate of congenital anomalies of the nervous system. This provided a possible neurodevelopmental basis for the finding that prenatal famine was associated with a doubling of the risk for schizophrenia (Susser *et al.*, 1996). More recent work carried the science further forward through a comparison of epigenetic findings for individuals prenatally exposed to famine and their unexposed same-sex siblings (Heijmans *et al.*, 2008; Tobi *et al.*, 2009; Tobi *et al.*, 2012). The findings showed a lower level of methylation (a chemical change associated with epigenetics) of the locus for the insulin-like growth factor II. This effect was seen only in those exposed to famine early in pregnancy and was not found for those exposed later in the pregnancy. Interestingly, the differences were found only in males. Animal models using mice have shown broadly comparable effects (Bale *et al.*, 2010; Monk *et al.*, 2013). Monk *et al.* (2013) have pointed out that the effects of maternal prenatal distress and poor nutrition have much in common and there is a lack of studies making a systematic comparison of these two risks.

Prenatal exposure to testosterone

The effects of testosterone on neurobehavioral development were first systematically studied by Phoenix *et al.* (1959) in an experimental study of the administration of testosterone to pregnant guinea pigs. Since then there have been a host of studies in a range of animal species (Hines 2004; Arnold 2009). The findings have shown an effect on the sexually dimorphic nucleus of the pre optic area and the inference has been that the hormone has an organizational effect on the brain, with consequent implications for behavior. There have been far fewer human studies of the effects of testosterone on the brain, although there are a number that deal with effects on gender-typical behavior. The main lack in the human research is a systematic examination of the link between neural sex differences and behavior sex differences. Hines (2011) concluded that the prenatal hormone environment contributed to both neural changes and behavioral changes but the effects were smaller than those found in the animal models. There are few demonstrated effects of female sex hormones on either the brain or behavior. A novel study of prenatal testosterone levels was provided by Vuoksima *et al.* (2010) through a comparison of left-handedness among females with male co-twins. The results do not deal directly with effects on the brain but they were suggestive of the effects of prenatal testosterone transfer.

Lombardo *et al.* (2012) studied the effects of fetal testosterone measured from amniotic fluid samples collected between 13 and 20 weeks of gestation in relation to MRI findings at the age of about 10 years. Higher levels of fetal testosterone were associated with local gray matter volume differences in brain regions congruent with sexual dimorphism. The findings were interpreted as suggestive of programming effect in humans but it should be noted that the study was done only in males and also other research (Moore, 2012) has shown weak associations between maternal testosterone and testosterone in the amniotic fluid.

Biological effects of prenatal stress

One study of infants exposed to higher levels of maternal plasma cortisol in the second and third trimesters had themselves a larger cortisol response to a heel-stick procedure (Davis *et al.*, 2011). Buss *et al.* (2010), in a prospective study, found that children exposed to maternal prenatal anxiety in the second trimester had a reduced gray matter volume in several areas involved with learning and memory. In another study, Buss *et al.* (2012) found that higher maternal cortisol levels in early pregnancy were associated with a larger right amygdala volume in girls but not in boys. Furthermore, higher maternal cortisol levels in early pregnancy were associated with more affective problems in girls that was partially mediated by amygdala volume. However, as Monk *et al.* (2012) pointed out, none of the available studies examined prenatal effects in the context of assessment of postnatal environment. In view of the continuities over time, that is a rather crucial omission. The effects of exposure to maternal distress during fetal development is highly correlated with continued exposure during postnatal

development and that raises the question as to how far changes in mother–child interaction postpartum play a role in the apparent effects of prenatal stress. Monk *et al.* (2012) suggested that, in keeping with animal models, the genetic effects may have important consequences.

In a rather different approach, Stevens *et al.* (2013) used a well-established animal model of prenatal stress (plexiglass restraint), and found that prenatal stress led to early disruption in GABAergic progenitor migration. Mychasiuk *et al.* (2011) studied the effects of prenatal stress in rats in order to examine possible variation in effects according to the severity of the stress. Mild prenatal stress increased global DNA methylation levels in the cortex and hippocampus, whereas high prenatal stress was associated with a dramatic decrease. This difference is in keeping with human studies, as well as other animal models, dealing with resilience (see Chapter 27).

Valentino *et al.* (2012) discussed stress and arousal in relation to sex differences in emotional disorders in humans. They pointed to the evidence that there were sex differences in the locus coeruleus (LC)-norepinephrine arousal system. Sex differences in LC dendritic structure have been found and these are of a kind that suggest that there may be increased receipt and processing of limbic information in females.

Entringer *et al.*'s (2011) study of the effects of prenatal stress exposure on telomere length (see subsequent text) in the offspring found that it was a significant predictor of a shortened telomere length in adulthood. The study is limited by the fact that it was a retrospective assessment.

In summary, there is evidence suggesting effects of prenatal stress on the brain, on epigenetics, and on HPA functioning. The evidence on epigenetics needs to take into account the cell-specific features of much in the way of epigenetic processes and all the prenatal effects have to be considered in relation to postnatal continuities from the prenatal period. Nevertheless, although we lack understanding of the details, clearly there are biological effects of prenatal stress.

Postnatal maltreatment

One of the methodological problems that dogs the whole of the literature on maltreatment effects derives from the fact that there is a massive co-occurrence between maltreatment and psychopathology. That makes it an important topic to study with respect to mental disorders but the difficulty arises from the fact that the physiological effects of adversity are very similar to those found with depression and anxiety (Heim *et al.*, 2008b; Frodl & O'Keane, 2013; Heim and Binder, 2012). Heim *et al.* (2008a) showed the importance of using subgroups without child abuse but with current depression, a group with depression but no history of abuse, and those with both. Regrettably, few studies have done this. However, studying inflammation effects, Danese and McEwen (2012, 2008) did do so (see subsequent text).

A further issue concerns the question as to whether all forms of maltreatment should be combined or whether a separation should be made between physical abuse, sexual abuse, physical neglect, and supervisory neglect (Pears *et al.*, 2008; Petrenko *et al.*, 2012). There may well be biological differences in the effects of these different forms of maltreatment but there are far too few studies to draw any valid conclusions on this. However, the biology of the effects of child abuse has been usefully brought together by McCrory *et al.* (2010, 2012). The findings suggest that child abuse is associated with atypical HPA axis functioning in a substantial minority of abused children and that this, in turn, tends to be associated with difficulties in emotional and behavioral regulation. The ongoing exposure to early adversity tends to be associated with stress habituation over time, leading to reduced cortisol levels rather than the elevated levels associated with acute stress.

Sapolsky *et al.* (1986) put forward a glucocorticoid-cascade hypothesis. This led on to McEwen's (2012) concept of allostatic overload concerning the toxic effect of prolonged HPA overactivity. Allostasis refers to the body's physiological response to adversity and threat. In practice, the allostatic load is indexed by features such as systolic blood pressure, urinary cortisol, catecholamines, waist/hip ratio, and high-density lipoprotein (HDL). In short, allostatic load/overload refers to an imbalance in systems that promote adaptation. However, the situation is complicated by the evidence of differences between children and adults (Lupien *et al.*, 2011). The evidence suggests that exposure to maltreatment is associated with reduced hippocampal volume in adults but not in children. Children exposed to postnatal maternal depression show significantly larger amygdala volumes. This has also been shown in studies of children reared in orphanages (see subsequent text). A study of rats has shown that environmental enrichment can mitigate chronic stress effects on hippocampal neuronal architecture (Hutchinson *et al.*, 2012). Although stress effects on the hippocampus differ between childhood and adult life, in both age groups there seems to be a smaller volume of the prefrontal cortex as a result of allostatic overload (Danese and McEwen, 2012). It is evident that the biological effects of stress experiences are quite complicated. Heim and Binder (2012) have argued that in addition to the features discussed, gene–environment interactions may also be influential.

Animal research has shown that the hippocampus plays a central role in learning and memory and these functions are impaired when animals are exposed to chronic stress (McCrory *et al.*, 2010, 2012). Thus, one might expect that, as with studies of adults with post traumatic stress disorder (PTSD) or with a history of maltreatment, the hippocampus should be smaller but this is not what is found in children. By contrast, the amygdala, which plays a central role in processing emotions, tends to show an increased volume. Moreover, these effects on the brain are not only found soon after the adversity has been experienced but they also tend to persist over time, in line with animal models. The findings on the effects on the prefrontal cortex are

somewhat inconsistent and it seems likely that there may be differences that relate to the age at which the abuse has occurred. A decreased volume of the cerebellum following maltreatment has been a consistent finding. Functional MRI (fMRI) studies have shown increased activation in the anterior cingulate cortex in young people who have experienced maltreatment, as compared with controls.

School-age children who have been exposed to physical abuse show increases in evoked response potential (ERP) brain activity specific to angry faces; see, for example, Pollak and Tolley-Schell (2003). One study (Andersen *et al.*, 2008) looking at MRI scans from 26 women with repeated episodes of childhood sexual abuse and 17 healthy controls found that the brain changes varied according to the age at which the abuse occurred. The findings require replication but it is likely that there will be age-related differences in neural effects. However, the Andersen *et al.* study was based on a relatively small number of subjects experiencing abuse at each stage and the sample excluded subjects with other forms of abuse such as witnessing domestic violence.

We have chosen to separate the effects of institutional deprivation from those of abuse despite the fact that there are important similarities between them. Early studies showed that whereas acute stress led to an increase in HPA activation, repeated stresses or chronic adversity usually led to a flattening in response (Gunnar & Vazquez, 2006). However, it is now evident that the situation is somewhat more complicated because there are differences between rodents and humans with respect to sensitivity to stress, and because in humans there are age-related and sex-related variations (Lupien *et al.*, 2009).

Telomere length

Telomeres are the repetitive TTAGGG sequence at the end of linear chromosomes. They are thought to function by capping and protecting the ends of chromosomes from DNA damage due to responses to stress and to aging. It is generally accepted that telomeres become shorter with each cell division and they have become established as a molecular clock for cellular replicative aging (Shalev *et al.*, 2013). Because telomeres have been thought to be adversely affected by stress, it has been suggested that they constitute a key part of the etiological pathways linking early life stress with inflammatory disease and aging (see Price *et al.*, 2013 for an overview). An important recent study by Shalev *et al.* (2013) used the British, nationally representative environmental risk (E-Risk) longitudinal twin study as a data source for examining the effects of exposure to violence during childhood. Telomere length was assessed at an age 5 baseline and age 10 follow-up. Four earlier studies had found an association between childhood adversity and shorter telomere length (TL) but there was one negative finding (Glass *et al.*, 2010). The Shalev *et al.* report has two important advantages over the earlier research. First, violence was assessed prospectively rather than retrospectively and, secondly, the changes in TL from baseline were examined as well as the overall association

with TL. The results showed significantly more telomere erosion between baseline and follow-up in children who experienced two or more kinds of violence exposure, the finding holding up after adjustment for sex, socioeconomic status, and body mass index. As Shalev (2012) pointed out, there are several different ways of measuring telomere length with continuing uncertainty as to which is the best. In addition, there may be differences according to whether TL is assessed in buccal cells (as obtained during a cheek swab) or blood products. The findings from Shalev *et al.* (2013) provide an important indication that TL may constitute a vital part of the pathways linking early life adversity and later disease but it should be noted that the study also showed that some children showed an increase in TL and it remains unclear whether that was simply a methodological artifact or reflected a meaningful change and, if it did, what influenced it.

Inflammation

Danese *et al.* (2008) used the Dunedin Multidisciplinary Health and Development Study (with a sample size of about 1000) where the follow-up was up to age 32 years in order to study inflammatory levels in individuals who had experienced maltreatment in childhood. Inflammation (referring to the body's response to trauma or infection) was assessed using high-sensitivity C-reactive protein and a dimensional inflammation factor indexing the shared variance of continuance measures of high-sensitivity C-reactive protein, fibrinogen, and white blood cells. The two measures of inflammation gave much the same picture. The key finding was that those who had experienced both maltreatment and depression showed a much increased level of inflammation as compared with either controls or a depressed only group (these two not differing significantly). Those with maltreatment only showed intermediate findings, leaving an uncertainty as to exactly what the combination of maltreatment and depression meant. The issue was further explored in a more recent study using the E-Risk Study that had the advantage of the prospective measure of maltreatment but the limitation of a follow-up only to age 12 years (Danese *et al.*, 2011). Like the earlier Dunedin study findings, the largest effect on inflammation was found in the depressed plus maltreated group. In this case, the maltreated-only and the depressed-only groups did not differ from controls. As Danese and McEwen (2012) pointed out, maltreatment leads to changes in the HPA axis and changes in the brain, as well as in the immune system. Quite how these different features relate to one another remains uncertain.

One of the queries regarding the lasting effects on inflammation concern the mechanisms that might be involved in its persistence over many years. A recent study by Cole *et al.* (2012) comparing peer-reared and maternal-reared rhesus macaque monkeys was informative in showing that peer-rearing was associated with enhanced expression of genes involved in inflammation, cytokine signaling, and T-lymphocyte activation; as well as suppression of genes involved in several innate

antimicrobial defenses. The study was limited by the lack of any direct measure of immune system functional activity but other analyses have shown that macaques exposed to the same adverse conditions in early life do show, as shown here, significantly elevated physical and behavioral sequelae (Conti *et al.*, 2012).

Institutional deprivation

Institutional deprivation has been dealt with here as a separate kind of experience because it involved a far greater and far wider level of deprivation than anything ordinarily experienced in family settings (Rutter & Sonuga-Barke, 2010). In addition, it did not necessarily involve individualized abuse. Rather, the key feature of the experience was neglect that involved both human interaction and conversation and global experiences. In the English and Romanian Study (Rutter & Sonuga-Barke, 2010), many of the children experienced marked subnutrition as well as psychosocial deprivation but it was possible to make comparisons between those who did and those who did not have subnutrition (Sonuga-Barke *et al.*, 2010; Rutter *et al.*, 2012). In the children without subnutrition, there was no impairment of head growth in children who left the institution before the age of 6 months but there was huge impairment of head growth in those whose institutional deprivation continued beyond the age of 6 months. It is known that head growth provides a good index of brain growth and therefore the strong inference is that the “pure” psychosocial deprivation led to major overall impairment in brain growth.

Sheridan *et al.* (2012), using data from the Bucharest Early Intervention project, compared children exposed to institutional rearing and children previously exposed to institutional rearing but then randomized to high-quality foster care intervention. There was also a comparison with typically developing children in Romania who were not in institutions. The findings showed that a history of institutional rearing was associated with a significantly smaller cortical gray matter volume. The effects on gray matter applied to those who had a history of institutionalization irrespective of whether they were later placed in foster care. On the other hand, cortical white matter did not differ between never-institutionalized children and children placed in foster care as part of the randomized design. The same study also looked at alpha frequencies in the overall electroencephalogram (EEG) signal. Children exposed to institutional rearing exhibited decreased alpha power, implying developmental delay in neural functioning. The association between institutional rearing and EEG alpha power was partially mediated by cortical matter volume for children not randomized to foster care. The alpha power finding (Marshall *et al.*, 2004) significantly moderated the associations between attachment security and social skills (Almas *et al.*, 2012). A separate study (Eluvathingal *et al.*, 2006) used diffusion tensor imaging in a study of children in North America adopted from Romania, showed a generally compromised white matter tract integrity. Yet another study

(Tottenham *et al.*, 2010) showed that prolonged institutional rearing was associated with an atypically large amygdala volume and difficulties in emotion regulation.

Bauer *et al.* (2009) compared post-institutionalized children from the Wisconsin International Adoption Project registry (meaning that these were volunteers) and controls acquired through community advertisements and flyers. The children were raised in orphanages in Romania, Russia, China and other countries—making it a somewhat heterogeneous group. The main finding was that the institutionally deprived group had smaller superior-posterior cerebellar lobe volumes than control subjects and that these two brain regions were related to two aspects of cognition. A smaller subgroup of the same sample was studied by Fries *et al.*, (2008) with the finding that the post-institutionalized children showed prolonged elevations in cortisol levels following a standardized interaction between the child and the mother, and not the interaction with a stranger. Results suggested that early institutional deprivation may contribute to long-term regulatory problems of the stress-responsive system, but these were evident only in the context of ongoing close interpersonal relationships. One limitation of the study was that it did not include a cortisol measurement immediately following the experimental session and hence it remains uncertain whether there was a hyperreactive response following the interaction, a prolonged response to the event, or both.

Studies from Carlson and Earls (1997) onward have shown that institution-reared children tend to show a low morning cortisol and a flat pattern of diurnal variation during the rest of the day. What has been somewhat uncertain is whether this dysregulation of the HPA axis persists after adoption. Kroupina *et al.* (2012) showed that it did persist, at least over the first 6 months (but with an increase in morning cortisol). The dysfunctional pattern was most evident in those who were stunted in their physical growth and the abnormal cortisol pattern was associated with externalizing behavior problems in adolescence and adults. Another study showed institutional rearing was associated with reduced telomere length (Drury *et al.*, 2011).

Conti *et al.* (2012) analyzed health records of rhesus monkeys across mother rearing, peer rearing, and surrogate peer rearing conditions, the latter being the closest to institutional rearing, and found that adverse rearing conditions had long-term detrimental effects on health that were not improved by subsequently improved rearing conditions (analogous to adoption).

Putting the available evidence together, it appears that the biological findings associated with profound institutional deprivation are broadly similar to those found with child abuse, but that what is different with institutional deprivation is the major effect on overall brain growth.

Social disadvantage

There is abundant evidence from cohort studies that social disadvantage in early life is associated with poor health in adult

life, even after adjusting for social status in adult life (Kuh *et al.*, 2002; Power *et al.*, 2005). The question that arises, therefore, is what biological mechanism underlies this persistence. The conceptual and methodological issues were well reviewed by Adler *et al.* (2012). The first problem is the need to check that the causal inference is justified and the second is that social disadvantage is an ill-defined concept that incorporates a wide range of circumstances—spanning low social status, poverty, neighborhood, and stresses of many varieties and behaviors (such as smoking, heavy drinking, and lack of exercise) that carry health risks. As such, the biological effects are likely to reflect those associated with each of these various features (many discussed in other sections of this chapter; see also Adler and Rehkopf, 2008).

Hertzman (2012) discussed the biology in terms of geographical variations in social vulnerability—noting differences in HPA axis functioning and event-related potentials assessing focused attention and epigenetic processes. Essex *et al.* (2011) reported epigenetic differences in adolescence associated with early adversity; and Lam *et al.* (2012) found some significant methylation differences in relation to social background—albeit with weaker effects than reported by Borghol *et al.* (2012) and by Miller *et al.* (2009). Numerous experimental animal models confirm the causal effects of social status on epigenetics (see Fernald & Maruska 2012; Mashoodh *et al.*, 2012). The study of epigenetics in humans is problematic in that effects tend to be cell-specific (not just tissue-specific) and developmental phase-specific. Nevertheless, it may be concluded that social disadvantage does have epigenetic effects in humans as well as other animals (Rutter, 2012a). However, the findings do not carry much clinical meaning unless it can be shown that the patterns of epigenetic findings can, at an individual level, differentiate between the different patterns of disadvantage, and between stress resistance and stress sensitivity to mention just two out of a much larger list of alternatives. That has yet to be determined.

Two small-scale imaging studies have examined neural correlates—one using structural imaging (Noble *et al.*, 2012) and one fMRI (Noble *et al.*, 2006). It is of considerable interest that individual differences in social status were associated with regional brain volume variations in the hippocampus and amygdala, and that reading levels were associated with responsivity in the left perisylvian and left occipitotemporal regions. However, as the authors note, the findings derived from a cross-sectional analysis with a small sample and that the direction of causality could not be assumed.

Enrichment and deprivation studies

Prompted by Donald Hebb's now classic book proposing the concept of use-dependent plasticity of the nervous system, Rosenzweig and his colleagues (1962) reported studies comparing rats reared under three different conditions. First, there was the standard colony situation with three animals in a standard

laboratory cage provided with food and water. Second, there was an impoverished condition in which the cages housed single animals only; and thirdly, animals housed in a large cage containing a group of 10–12 animals with a variety of stimulus objects, changed daily. Findings showed that differential experiences caused changes in cortical chemistry and in the weight of different regions of the neocortex. The findings were replicated by Greenough and Volkmar (1973). The early studies of enrichment and deprivation were undertaken with juvenile rats, with the expectation that plasticity might be confined to early life. However, later studies showed that closely comparable (although lesser) effects were found with adult rats (Rosenzweig & Bennett, 1996). Although the capacity for plastic changes to the nervous system remained in older animals, the effects of differential experience developed more rapidly in younger animals, with the effects being larger in the young.

These findings on enrichment and deprivation derived from animal models were later studied in humans. The human studies involved several different developments. First, there were comparisons of the relative efficacy of environmental enrichment, physical exercise, or formal training (see, e.g., van Praag *et al.*, 2000; Will *et al.*, 2004). Overall, the evidence suggested that specific training was more effective than physical exercise and that enriched experience was more effective than either of the other two. The other development involved the extrapolation of the findings to what might be done to enhance recovery after neurological damage (Taub *et al.*, 2002). While it was clear that the general principles applied as much to recovery from brain injury as to effects in normals, it remains uncertain how far the benefits come from neuronal regrowth following intervention. One recent study using an animal model (involving partial transection of the spinal cord) suggested that there could be neuronal regrowth (van den Brand *et al.*, 2012), but the finding requires replication and human studies have yet to be undertaken. It also remains to be seen whether the evidence that environmental enrichment enhances neurogenesis (growth of nerve cells) in the adult hippocampus (Kempermann, 2008) is relevant for the concept of brain and cognitive reserve in relation to brain disorders (Nithianantharajah & Hannan, 2009). Further research is also needed to identify the molecular mechanisms involved in plasticity at different ages (Bavelier *et al.*, 2010).

Human studies of the effects of learning on the brain in adult life hit the headlines with Maguire *et al.*'s (2000, 2006) study of structural differences in the hippocampi of London taxi drivers as compared with bus drivers and controls. London taxi drivers are distinctive in being required to undergo extensive training followed by a test of “The Knowledge” involving the learning of the layout of some 25,000 streets and many thousands of places of interest. Compared with controls, the taxi drivers had a larger gray matter volume in the posterior hippocampus and a smaller volume in the anterior hippocampus. Because this was not an experimental study, it was not possible to rule out the possibility that taxi drivers who passed “The Knowledge” had a hippocampus that was different before the

training started. However, the taxi drivers and their controls generally had average IQs (Woollett *et al.*, 2010). Later research went on to show that retired taxi drivers had a hippocampus pattern similar to practising taxi drivers but the pattern became closer to controls. In other words, although the effects of the intense prolonged training were lasting, they were not permanent.

Somewhat similar findings are evident in studies of musical training, except that the changes were in the motor and auditory areas critical for music training rather than the hippocampus (Elbert *et al.*, 1995). In this case, longitudinal data were used to test the hypothesis that the cerebral differences truly reflected the effects of training rather than preexisting brain differences. Hyde *et al.*, (2009) showed that there were no differences in the brain between young children who received 15 months of instrumental musical training compared with a group of children who did not. However, there were significant differences in the brain after training and, moreover, these were correlated with behavioral improvements. What this study did not do, because it was concerned with children, is test whether the same would apply to training in adult life.

A study of jugglers undertaken by Draganski *et al.*, (2004; Draganski & May, 2008) did show training-induced structural brain changes in adults. The music and the juggling studies are also crucial in their demonstration that the brain changes applied to areas of the brain other than the hippocampus.

Experience-expectant effects

Vision

As indicated, the biological effects of most experiences are not dependent on a narrowly defined sensitive period. However, there are exceptions. The Hubel and Wiesel studies during the 1960s, (summarized in Hubel & Wiesel, 2005) were crucially important in showing that visual input was essential for the normal development of the visual cortex. These findings with cats have sometimes been considered to deal with a mechanism that applies more generally to brain development. The evidence clearly indicates that it does not, although it is likely that effects are not only confined to the visual system.

Hubel and Wiesel (2005) showed clearly, in a series of experiments with kittens, that profound sensory deprivation had a major effect on the development of the visual cortex. Kittens underwent monocular deprivation (i.e., one eye was sewn shut) during a critical period of visual development. Ordinarily, this period (4 weeks–3 months) corresponds to a period of preprogrammed ocular dominance but, with monocular deprivation, profound visual impairment was seen after the deprived eye was opened. Crucially, these effects were not seen if the deprivation occurred later (e.g., at 3–4 months). It seemed that the cortical areas functioned in relation to a competitive interaction between environmental inputs received during critical periods, rather than preprogrammed representation only. These findings, which resulted in a Nobel Prize, demonstrated the remarkable

plasticity (modifiability) of the brain for the first time (Bryck & Fisher, 2012).

Pollutants

A study by Herr *et al.* (2010) showed that maternal exposure to pollution had an effect on the balance between T lymphocytes and B lymphocytes, which was interpreted as meaning an effect on immunity. This was seen only in early gestation. Evidence reviewed by Perera and Herbstman (2011) suggests that the prenatal effects may be concerned with regulating the fetal epigenome but, although plausible, the suggestion so far lacks empirical support. Also, implications for later consequences of these prenatal effects from pollutants remain quite uncertain.

One of the main groups of pollutants concerns endocrine disrupting compounds (EDCs) (DiVall, 2013). The findings on biological effects well illustrate the problems in assessing any pollutant. The National Toxicology Program (NTP) panel noted the uncertainties regarding both the epidemiological evidence and the animal studies. The NTP expressed negligible or minimal concern regarding most claimed ill effects (including those on birth weight and growth). However, it was noted that prenatal phthalate *might* predispose to congenital disorders of much reproductive tract development.

The Mexican studies (Calderón-Garcidueñas *et al.*, 2013) suggested that air pollution in Mexico City involved particulate matter metal neurotoxicity leading to a neuroinflammatory response and neural effects. However, the sample size was small and this is best considered as only a possibility warranting further study.

Lead

Rutter (1983) reviewed extensive evidence on low level lead exposure—with a major focus on the behavioral sequelae but also with attention to the biological findings. He noted that it had long been known that lead is a neurotoxin and that lead poisoning can cause encephalopathy and death. He concluded that there was no clear threshold below which there were no neural effects. Human evidence showed that blood/lead levels greater than 50 µg/dL, and probably at levels below that, led to impaired nerve conduction velocities. Similarly, children with raised lead levels had significantly increased amounts of low frequency delta activity on the EEG. One investigation also showed that slow wave voltage varies as a linear function of blood lead level. Animal studies are important in terms of the evidence that lead inhibits the heme biosynthetic pathway with effects measureable at lead levels below 30 µg/dL. In addition, lead has effects on several neurotransmitters and has been found to delay brain development in rat pups exposed to quite modest levels of lead in the neonatal period. It was concluded that increased levels of blood/body lead can and do cause impairment of biological functioning at levels well below those associated with recognizable signs and symptoms attributable to lead toxicity.

During the 1990s, a meta-analysis showed that there was a decline of 2–3 points for every 10 µg/dL increase in blood level (Schwartz, 1994). This was, however, based on studies in which most children had blood-lead levels in the range of 10–30 µg/dL. The situation since the 1980s and 1990s has changed greatly so that in most general populations the mean blood-lead level is now well below 10 µg/dL and sometimes it is as low as 1–2 µg/dL. Accordingly, the issue is whether lead has important adverse biological effects in this low range (Bellinger, 2008). The recent population-based brain imaging study by Cecil *et al.* (2008) found dose-dependent decreases in the volume of gray matter in the ventrolateral prefrontal cortex, the anterior cingulate cortex, the postcentral gyri, the inferior parietal lobule and the cerebellum, the reduction being particularly striking in males. Because this was an observational study, firm conclusions on causality were not possible. However, they attempted to get a handle on this by determining whether the brain changes were associated with neuropsychological functioning—with the finding of a lack of clear structure–function correlates, except in the case of motor skills. The conclusion now, unfortunately, has to be much the same as it was in the early 1980s. That is, there is no clear point below which there are no risks from lead toxicity but, equally, the effects are slight within a range of lower lead levels.

Traumatic brain injury

The first controlled, prospective psychiatric interview study of traumatic brain injury in children was undertaken by Rutter and colleagues in the late 1970s (Brown *et al.*, 1981). At that time brain imaging was not available and there had to be reliance only on duration of post traumatic amnesia as an index of the severity of the injury. There was good evidence that severe head injury played a crucial causal role in the development of psychiatric disorders arising during the 27 months subsequent to the accident but the risk was significantly influenced by the children's pre-accident behavior, their cognitive level, and their psychosocial circumstances. The only disorder specifically associated with the injury was a disinhibited state—a pattern that did not fit in with the usual psychiatric classifications at that time. A recent study by Max *et al.* (2012) took an understanding of the biology further through its use of diffusion tensor imaging (DTI)-derived fractional anisotropy (FA) and other brain imaging measures. The findings showed that new psychiatric disorders were not significantly related to volumetric measures of white or gray matter structures, volumetric measures of lesions or cortical thickness measures, but they were related to FA. It was concluded that lowered white matter integrity may be important in the pathophysiology of new psychiatric disorders following traumatic brain injury. It was notable that almost all the novel psychiatric disorders involved personality change—a finding in good keeping with the earlier study by Brown *et al.* (1981) showing disinhibited behavior.

Biological effects of different therapeutic interventions

There has long been an interest in the biology of depression (Mayberg, 2003; Nestler & Carlezon, 2006). The hope has been that treatments may alleviate symptoms through correction of dysregulated neural circuit activity (Ressler & Mayberg, 2007). Goldapple *et al.* (2004) reported a small study using functional brain imaging in which the findings suggested that cognitive behavior therapy (CBT) had a different neural effect than paroxetine, an antidepressant medication. Mayberg *et al.* (2000) noted changes in brain glucose metabolism measured using positron emission tomography (PET) in patients treated with fluoxetine that paralleled the clinical response. On the other hand, research also showed that imaging findings indicated that common regions of brain activation were targeted with pharmacological and somatic treatments as well as with emotional learning in psychotherapy (Ressler & Mayberg, 2007). Nemeroff *et al.* (2003) found that the effects of CBT and antidepressants were broadly similar but that responsivity did seem to be influenced by a history of childhood maltreatment. Tremblay *et al.* (2005) showed that individuals with a major depressive disorder had a hypersensitive response to the rewarding effects of dextroamphetamine, with altered brain activation in the ventrolateral PFC and the orbitofrontal cortex and the caudate and putamen.

We conclude that cognitive therapy and antidepressant medication of various sorts probably engage somewhat similar neural mechanisms although there may well be some mechanisms that are distinctive to each (DeRubeis *et al.*, 2008). It is necessary to be mindful, however, of the substantial conceptual, methodological, and statistical problems using brain imaging of all kinds in order to infer causal effects (Peterson, 2003), especially in relation to interventions (Bishop, 2013). There is little doubt that treatment is associated with a change in the neural features associated with depression and anxiety but some of these changes are also seen in people given placebos. In short, are the supposed treatment effects cause or consequence? In seeking to answer that question, it is necessary also to bear in mind that depression is associated with a somewhat heterogeneous range of biological differences (Ressler & Nemeroff, 2000).

Gene–environment interaction (G × E)

There is a wealth of data showing the reality of G × E based on research conducted with multiple species and from research using both observational and experimental methods (Rutter, 2006; Caspi *et al.*, 2010; Rutter, 2012b; Rutter, 2014). This is well summarized in State and Thapar (see Chapter 24). The focus in this chapter, however, is exclusively on the biology of the G × E effects.

These have been shown most clearly in the human experimental studies undertaken by Weinberger, Meyer-Lindenberg, Hariri and Pezawas (Hariri *et al.*, 2002; Hariri *et al.*, 2005; Pezawas *et al.*, 2005; Meyer-Lindenberg *et al.*, 2006;

Meyer-Lindenberg & Weinberger 2006; Buckholz & Meyer-Lindenberg 2008). All of these studies were undertaken with normal volunteers who had been screened to be free of psychopathology. This had the important consequence that the findings applied, not just to patients with particular mental disorders but to the population as a whole. The findings apply to both the MAOA genotype and to the serotonin transporter-linked polymorphic region (5-HTTLPR) with the former concerned predominantly with impulsive violence and the latter with anxiety and depression. It is striking, however, that the impact on the structure and function of the amygdala (with increased reactivity) and the perigenual cingulate cortex, which implies a shared mechanism of emotional regulation under serotonergic control applied to both. Nevertheless, the MAOA genotype showed much more extensive effects on both structure and activation notably affecting more caudal regions of the cingulate associated with cognitive control, as well as the orbitofrontal cortex and hippocampus. All of these findings were derived from structural and functional magnetic resonance imaging (sMRI and fMRI respectively) and DNA findings on the genotype. The increase in bilateral orbitofrontal cortex was evident only in men. The 5-HTTLPR findings were associated with reduced gray matter volume in short allele carriers in limbic regions critical for the processing of negative emotion—particularly the perigenual cingulate and amygdala. Functional analysis during perceptual processing of fearful stimuli demonstrated tight coupling as the feedback circuit, the short allele carriers having a relative uncoupling of this circuit.

Nonhuman primate studies have shown that the $G \times E$ is associated with an increased HPA axis response to stress in infant macaques (Barr *et al.*, 2004). Rodent studies have been informative, through the study of genetically engineered 5HTT mutations. They have shown that the neural consequences extended well beyond the regulation of 5HTT availability. There were alterations throughout the system, in which the 5HTT knock-out mice exhibited an abnormally high density of excitatory dendritic spines on amygdala neurons and an increase in dendritic arborization of the prefrontal cortex neurons. This implication was confirmed in a rhesus macaque model (Jedema *et al.*, 2010). The last point to make is that many people have assumed that the $G \times E$ applies to responsivity to adverse experiences. However, it has been argued—particularly by Boyce and by Belsky—that evolutionary considerations suggest that it is more likely that it involves an increased sensitivity to the environment both good and bad (Ellis *et al.*, 2011). The evidence in support of this suggestion is growing, although it is still a bit too early to regard this as established. Nevertheless, it seems increasingly likely that it may prove to be valid.

Overall conclusions

Four key issues apply to all the biological effects discussed in this chapter. First there is the question as to whether the

associations with experiences truly represent a causal influence of experiences on the biology. Second, there are questions on the specificity of the biological effects. Third, there is a lack of knowledge on the connections among the different biological features. Fourth, there is the question as to whether the biological features are responsible for the consequent effects on psychopathological functioning.

The causal inference has been considered in several different ways. To begin with, it has often been possible to use animal models and, where they have been available and relevant, we have briefly summarized the findings. In addition, we have paid attention to specificity of timing. Thus, this applied to the effects of exposure to maternal alcohol, to smoking and to testosterone. Also, in the few instances where such data were available, we noted the use of prospective data to look at changes in the biology as found following experiences. That applies, for example, to the telomere length research. There are not many instances where natural experiments have been available but they were informative with respect to the separation of prenatal from postnatal effects using adoptee data. Lastly, we have made use, whenever available, of the additional leverage provided by bringing together different measures. For example, this was useful with respect to the neural effects of institutional deprivation—as shown by the combination of MRI findings and alpha strength on the EEG. We conclude that the causal inference has had reasonable, albeit modest, support for most of the biological findings we have considered.

The second major issue concerns the specificity of the biological effects. What is immediately striking is that all clinically significant experiences have been shown to have biological effects. In some cases, questions remain on whether very mild experiences have measurable effects, but it is evident that if there is a threshold on dosage it must be a very low threshold. What is also very striking is that there is a huge diversity of biological consequences—including epigenetic effects, HPA axis effects, impact on telomere length, effects on the hippocampus, the amygdala and the cerebral cortex, on overall brain growth, on inflammation, and on birth weight. In addition, there appears to be variation according to sex, to the individual's age at the time of the experience, and to the specifics of the nature of the experience. There is likely to be an understandable meaning to the causes of this heterogeneity but, although good ideas have been put forward, there is no consensus so far on the mechanisms. Furthermore, the research undertaken so far has not provided a clear differentiation between the biologically negative consequences of adverse experiences and the biological changes that represent positive adaptational changes underpinning resilience.

Third, there is still a lack of understanding of the relationship among the various biological features. How, for example, do the epigenetic changes relate to the HPA effects and how do both of these relate to inflammation and telomere findings? The precise neural effects (such as between the hippocampus and the amygdala) seem to vary between children and adults. Is this because

of structural and functional changes in the development of the brain, or do these reflect age-related variations in experiential effects? Clearly, much remains to be learned. Finally, major questions remain on the functional implications of the biological findings—particularly with respect to their role in the psychological and psychopathological outcomes of the experiences—as discussed by Rutter (2012a).

CHAPTER 24

Genetics

Matthew W. State¹ and Anita Thapar²

¹Department of Psychiatry, Langley Porter Psychiatric Institute, University of California, San Francisco, CA, USA

²Child and Adolescent Psychiatry Section, Institute of Psychological Medicine and Clinical Neurosciences, Cardiff University School of Medicine, Cardiff University, UK

Introduction

The past few years have heralded a new era in psychiatric genetics. After several decades of halting progress, a phase of steady and rapid advance is leading to consensus on a range of issues, including the identification of specific risk genes. These discoveries are paving the way for a deeper understanding of population risks, molecular, cellular and circuit-level mechanisms underpinning psychiatric pathophysiology and identification of novel treatment targets.

It is clear that identified genetic factors typically operate in a probabilistic fashion, increasing the risk for, rather than determining symptoms. Moreover, identical genetic mutations may lead to a range of psychiatric outcomes, defying the current psychiatric diagnostic nosology. These complexities, coupled with the rapid pace of gene discovery, mean that practicing clinicians will need to remain up to date on the basics of genetics and recent progress.

DNA, genes and chromosomes

DNA

The human genome is composed of DNA, deoxyribonucleic acid, which is in turn comprised of a sugar phosphate backbone and four nitrogenous bases: adenine (A), thymine (T), guanine (G), and cytosine (C). The structure of DNA is the well-known double helix: at each base position in the DNA code, there is both a base and a specific complementary base forming a “base-pair” (Figure 24.1). In human cells, the majority of hereditary material is carried in the nucleus and is referred to as the nuclear genome. It is ~3 billion bases long when counted end to end and contains about 21,000 genes. Human cells also contain a much smaller mitochondrial genome (~17,000 bases) in a single double stranded circular DNA molecule that is inherited through the maternal line.

Genes

The definition of a gene continues to be refined. In the late 1950s, a gene was conceptualized as a DNA sequence that was transcribed into a messenger ribonucleic acid (mRNA) and then translated into a protein (Figure 24.1). However, as the understanding of genomics has advanced, numerous exceptions to this definition have been identified. For example, DNA sequences may lead to transcribed RNA that is not translated into protein but has important biological functions nonetheless. Thus, a more contemporary notion of a gene is a code contained within the nucleic acid that gives rise to a functional product.

The characterization of all DNA elements and their function, including what was previously thought to be “junk DNA” between genes, is the goal of the international collaboration ENCODE (<http://genome.ucsc.edu/encode/>). However, for the sake of the current discussion, we focus largely on genes that code for proteins. These comprise only about 1% of the genome (~30,000,000 bases) and are collectively referred to as the “exome.” Individual genes include multiple component parts (Figure 24.1). In addition, upstream of protein-coding genes are classical “promoter” elements that regulate gene expression. There are also regulatory regions widely distributed throughout the genome that can result in increased gene expression (enhancers), decreased gene expression (silencers), or provide boundaries between these two types of elements (insulators). In addition, DNA sequences, often in the 3′ untranslated region (UTR; Figure 24.1), that bind to small RNA molecules, called microRNAs, can regulate gene expression.

Chromosomes

The human genome is organized into 23 pairs of chromosomes. Each nuclear chromosome pair consists of one from the paternal lineage and the other from the maternal line. Pairs 1–22 are referred to as “autosomes,” numbered from largest to smallest based on the length of the DNA strand. There is also one pair

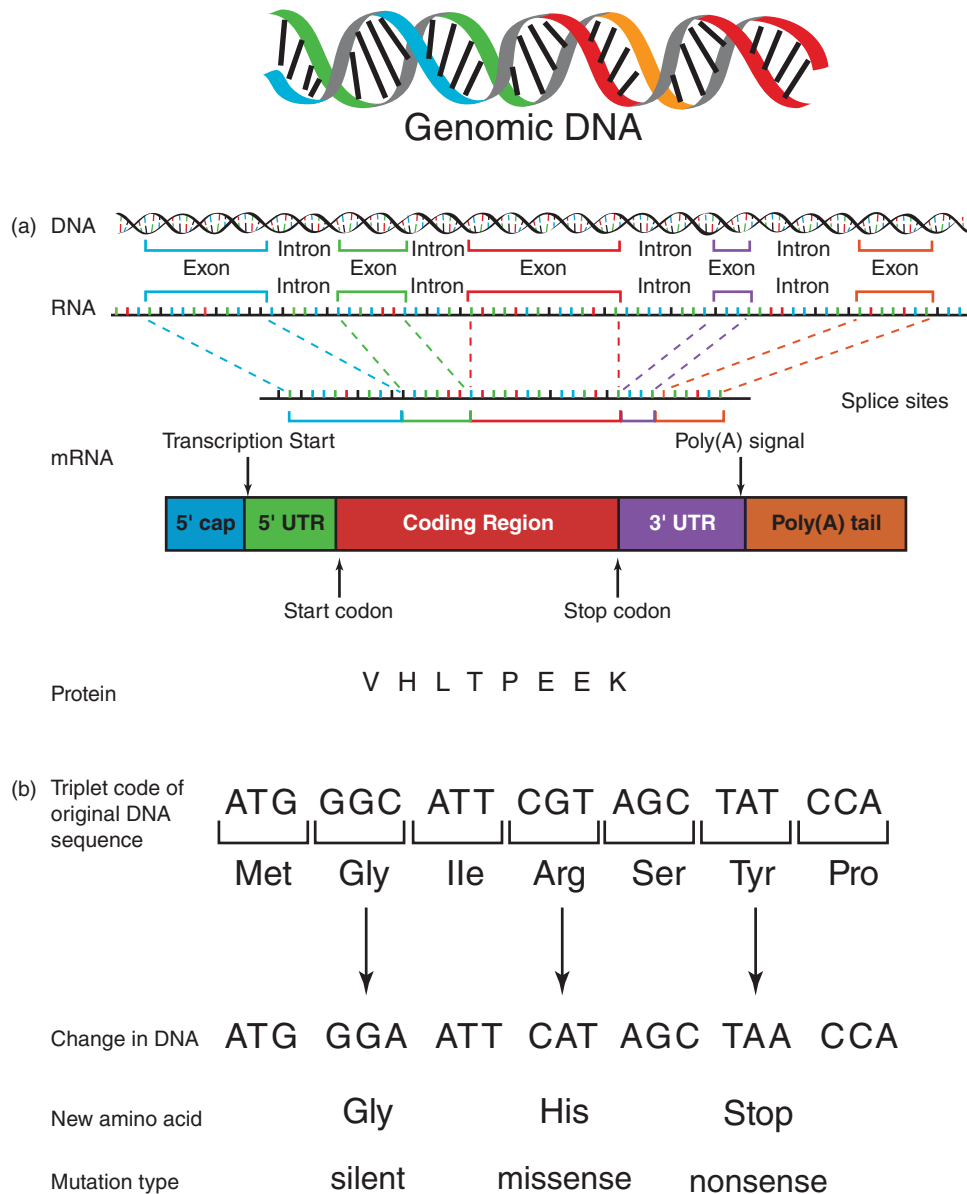

Figure 24.1 DNA, Transcription, and Translation

(a) The double helix structure of DNA is shown at the top. The translation of DNA to RNA to protein is diagrammed moving from top to bottom. The majority of human genes consist of multiple “exons”; segments of DNA that contain a series of three-letter nucleotide codes (codons) that specify individual amino acids. These are interspersed among “introns,” which do not specify amino acids. The central dogma is that DNA (a) is transcribed into RNA and then translated into protein. In transcription, introns are spliced out of the gene, leading to the specification of a full-length mRNA that encodes a specific protein. In addition to the “coding portion” of the gene, additional sequence motifs are present in the DNA and remain in the mRNA including a region immediately upstream of a translation start site, known as the 5′ untranslated region (UTR) and a region just beyond the “stop codon” specifying the termination of translation. These regions are known to be involved in the regulation of gene expression. (b) Variations in the genetic code may lead to several classes of amino acid “substitutions.” As the genetic code contains redundancies, some changes in the code of the DNA will not result in an amino acid change (GLY to GLY in the diagram). This is referred to as a “silent” mutation. When a nucleotide change alters one amino acid to a different amino acid, this is known as a “missense” mutation (ARG to HIS in the diagram). When a change in sequence results in the code for an amino acid changing to a termination (or stop) codon, the mutation is referred to as a nonsense mutation. Amino acid abbreviations: V = valine; H/his = histidine; L = leucine; T/tyr = tyrosine; P/pro = proline; E = glutamic acid; K = lysine; Met = methionine; gly = glycine; Ile = isoleucine; arg = arginine; ser = serine.

of sex chromosomes (X and Y). Mitochondrial chromosome is transmitted via the maternal line.

Chromosomes also contain proteins called histones around which the DNA is coiled. This combination of DNA and protein is referred to as chromatin. The compactness of the chromatin varies throughout the cell cycle. Chromosomes are particularly tightly condensed during metaphase, which renders them visible under the light microscope, as is seen in the typical karyotype. The degree of coiling or condensation of chromatin may be regulated, via a number of processes, including (but not limited to) chemical modification of the DNA through methylation, as well as histone protein modification, via acetylation, methylation, and phosphorylation. These processes regulate gene expression in part by regulating the “access” of the transcriptional and regulatory machinery to the DNA, and play a key role in epigenetics (see Chapter 25). These epigenetic mechanisms also contribute to genomic imprinting whereby the expression of a given gene or genes is silenced depending on the parent of origin; defects in this process can result in a range of important disorders such as Prader Willi syndrome (see Chapter 54).

Genetic variation and its detection

Genetic variation

Any two individuals are identical across ~99% of their genetic material. It is the 1% of the genome that varies that is a main preoccupation of those interested in disease risk, with the key question being how the DNA among affected individuals varies from those who are not at risk.

There are several important categories of variation. It has long been known that the sequence of the DNA varies between individuals. However, the fine structure of chromosomes also commonly varies between individuals. Indeed, genomes contain many regions, consisting of a thousand to several million bases of DNA, that are either missing or increased in the number of copies relative to a reference genome (Figure 24.2). When these changes remain below the level of detection afforded by the light microscope, they are referred to as copy number variants (CNVs).

A second important characteristic of DNA variation, whether sequence or structural, is its frequency in the population: variation is considered common when it exceeds an arbitrary threshold (typically 1% of individuals). Conversely, variation that does not reach this frequency is termed rare. These categories turn out to be relevant biologically. As a rule of thumb, variation that is common in the genome tends to carry smaller biological effects relative to variation that is rare in the genome (Figure 24.3).

It is also useful to review the nomenclature describing the frequency of variation: Single base changes in DNA present in more than 1% of a reference population are typically referred to as single nucleotide polymorphisms (SNPs). Rare single base changes are often referred to as single nucleotide

variants (SNVs). Changes in copy number variation common in the population are sometimes referred to as copy number polymorphisms (CNPs) as opposed to CNVs, which is a term most often used to refer to rare structural variation.

A third important distinction revolves around the temporal origin of the genetic variation. A variation present in a prior generation and passed from that generation to the next is termed “transmitted” variation. In contrast, in the generation in which a mutation first occurs, it is referred to as a “*de novo*.” If a spontaneous mutation occurs in a germ cell (egg or sperm) prior to conception and that egg or sperm is fertilized, then the mutation would lead to “germ line” *de novo* variation in the offspring. It will be present in every offspring cell but will not be detectable in their parents. Alternatively, if the mutation arises post conception, this somatic mutation is not present in every cell of the individual. Finally, when a somatic mutation occurs in the parent germ line and is not detectable more generally in the parent, it is referred to as a germ line mosaicism. This may lead to more than one child in a family with what appears to be a germ line *de novo* mutation.

Detecting variation

Currently, three broad types of DNA assays are in wide use. These include genotyping, sequencing, and copy number variation detection.

Genotyping evaluates for the presence or absence of a known genetic (typically sequence) variation. Initially, due to technological hurdles, genotyping assays involved one or a small number of SNPs, placing practical limits on the number of variations that could reasonably be assayed in a given experiment. However, the development of microarray technology resulted in the dramatic expansion of genotyping capacity, allowing currently, the simultaneous testing of millions of SNPs rapidly and at low cost.

DNA sequencing, in contrast to genotyping, involves the elaboration of the genetic code at each position in the genome, without the requirement of knowing, in advance, the identity of the base in the reference genome or the range of possible variations. The details of “next generation sequencing” are beyond the scope of this chapter. In 2013, it is now routine to sequence all 30,000,000 bases in the human exome for less than \$1000 per person, a price point that is considered an approximate upper limit for feasible large-scale studies supported by traditional funding mechanisms. The cost of sequencing the entire 3 billion bases in the human genome is rapidly approaching this threshold.

Chromosomal copy number is currently typically evaluated either by comparative genomic hybridization (CGH) or genotyping microarrays (Figure 24.2). Importantly, both approaches infer copy number states from fluorescence signal in a way that, particularly for detection of *de novo* variation, often requires confirmation via an alternative method.

Next generation sequencing technology can also be used to assay copy number. These sequencing methods involve oversampling of DNA data to ensure that a complete picture

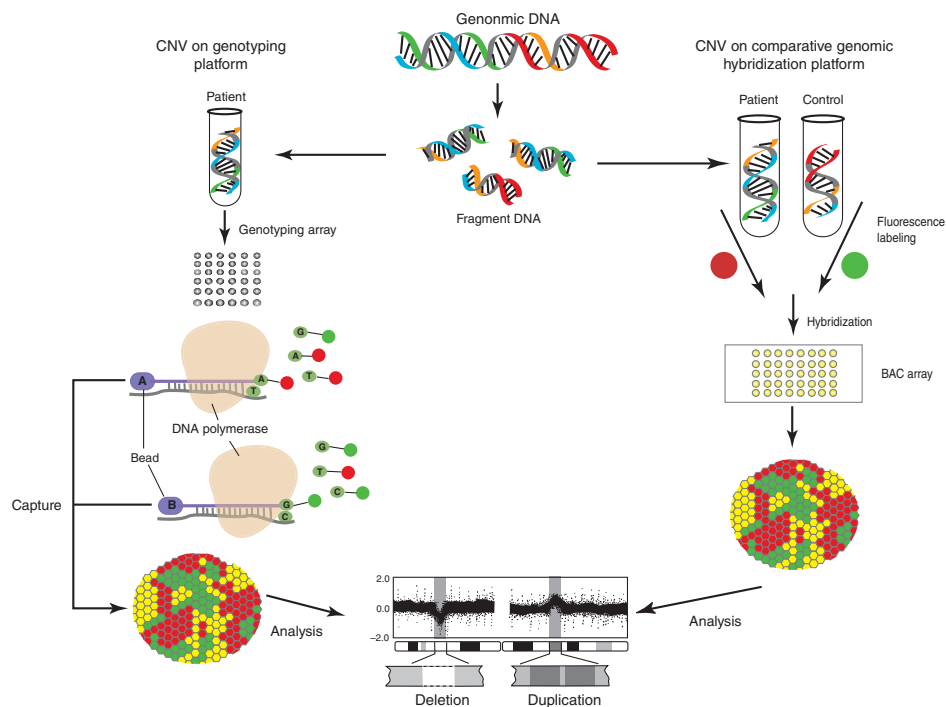

Figure 24.2 Microarray-based Copy number variation detection

Two commonly used methods for the detection of copy number variation are diagrammed. On the left, the use of a genotyping approach is shown. In this method, DNA only from a patient is used. Sheared DNA is prepared and hybridized to synthetic oligonucleotides maintained on a solid substrate (a microarray of beads in this figure). These synthetic nucleotides are specific sequences that bind to cognate sequences in the patient DNA. A single base reaction then takes place in the presence of fluorescently labeled nucleotides. The incorporation of a given nucleotide base leads to the incorporation of a distinct fluor depending on the sequence of the patient DNA at that position. Consequently, this platform provides genotyping data. In addition, there are many copies of each synthetic oligonucleotide on the array. The amount of input DNA from the patient can be inferred by the strength of the fluorescence signal that results. The signal is compared to a large group of controls that have been genotyped on the array. This signal strength for the subject is displayed relative to that from the group control (shown at the very bottom of the diagram). The right side of the figure shows a comparative genomic hybridization array. In this method, sheared patient and control DNA (either an individual or a group of controls) is prepared and hybridized to an array containing segments of the human genome (currently, typically carried in bacterial artificial chromosomes (BACs)). Patient and control are tagged with different fluorescence probes. The relative amounts of the patient signal and the control signal are then determined. An increase in patient signal is predicted to be a duplication or further amplification of the DNA copy number, and a relative paucity of patient DNA is inferred to be a deletion. For both types of assays, the inferences from the relative fluorescence signal may be subject to some confirmatory process either through a repeat or alternative assay.

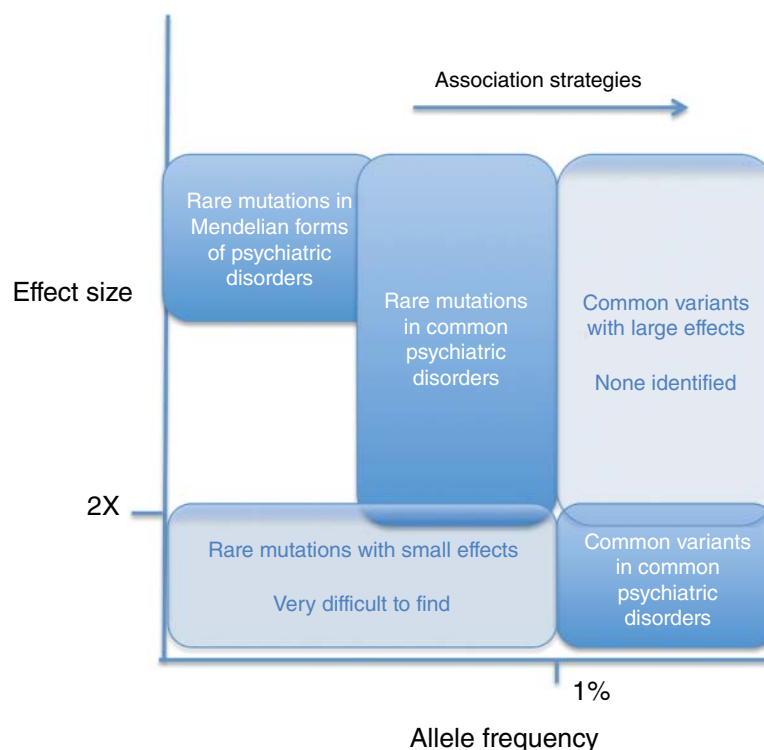

Figure 24.3 *Allele Frequency and Effect Size*

The figure provides an overview of the relationship between allele frequency and effect size in human disease, in this case psychiatric illness. Examples of Mendelian forms of psychiatric phenotypes have been identified in which a single gene is very strongly related to a specific definable phenotype. These involve very rare mutations generally carrying large effects. Their contribution to population risk for psychiatric disorders is limited. However, gene identification in these circumstances may provide avenues to identify molecular mechanisms relevant for more common forms of a disorder. Rare mutations have also been identified increasingly in common forms of psychiatric conditions. These have generally been found to confer intermediate risks and to do so in a probabilistic fashion (as shown in the diagram). Finally, specific common variations have been found to carry risk for several common psychiatric conditions, including schizophrenia and bipolar disorder and are highly suspect, but not yet confirmed, in others including autism, ADHD, and depression. These alleles are, by definition, common in the population and so far have been found to confer very small risks. Given the theoretical ease of finding common variants carrying large risks, the absence of such findings suggests that few, if any, of these types of variations will be found contributing to common psychiatric disorder. In a similar vein, rare variants carrying small risks may be relevant for psychiatric illness, but are likely to be impossible to find given limits on sample size.

of genetic variation is captured for every base. The number of “reads” produced for each interval is proportional to the amount of starting material in the reaction. Consequently, both read “depth” as well as an analysis of changes in the sequence output relative to a reference genome, can provide information regarding copy number changes as well as chromosomal rearrangements (e.g., inversions and translocations)—something that most common array-based CNV methods cannot detect.

Relating Genes to Behaviors

Genetic epidemiology

In traditional genetic epidemiological designs, the contribution of genetic factors is inferred rather than directly measured. This is achieved by assessing phenotype similarity between individuals who differ in genetic relatedness. A significant genetic contribution for a given trait or disorder is inferred when there is greater similarity between those who are more

closely genetically related versus those who are less closely related or unrelated. These traditional designs were initially important in demonstrating the contribution of familial and genetic influences to different psychiatric disorders. Subsequently they have proven useful for assessing a broader set of questions, for example, to test causal environmental risks (see Chapter 12), and gene–environment interplay (Rutter, 2012). More recently, traditional designs are being used to investigate biological questions (van Dongen *et al.*, 2012); for example, the contributions of DNA and epigenetic variation.

Family studies

These involve investigating whether the relatives of those with a given disorder show an increased rate of that disorder when compared with relatives of controls. These early studies demonstrated that psychiatric disorders show familial clustering although the magnitude varies for different disorders. For example, relative risks of a first-degree relative (e.g., parent, child, sibling) having the same disorder as the proband are

around 2–4 for child and adolescent depression (Rice *et al.*, 2002), around 2–8 for ADHD (Attention Deficit Hyperactivity Disorder; Thapar *et al.*, 2012) and rates of recurrence in siblings of those with autism are around 25 times higher than in the general population (Devlin & Scherer, 2012).

Challenges with regard to developing precise estimates of familial risk include changing estimates of population prevalence over time, difficulties in establishing precise diagnostic boundaries, and taking into account phenotypes that may either emerge or change in character across development. The patterns of familial transmission observed in early family studies paved the way for modern molecular genetic studies and showed that psychiatric disorders, like other common diseases, were complex and multifactorial in origin.

Relatives share environments as well as genes. Consequently, family studies are unable to distinguish whether any observed aggregation is a consequence of shared environmental exposures or shared genetic risks. Twin and adoption study designs are thus a critical complement to help distinguish genetic and environmental influences.

Twin designs

The twin design is based on the premise that monozygotic (MZ) twins are genetically identical, whereas dizygotic (DZ) twins share on average 50% of their genes. A genetic contribution to a trait or disorder (phenotype) is inferred where MZ twins show greater similarity than DZ twin pairs for the phenotype in question. This similarity is indicated by higher MZ than DZ correlation coefficients for trait measures, and significant MZ–DZ differences in proband-wise concordance rates for categorical measures.

Data from such studies can be used to disaggregate phenotype variation (Falconer, 1989) in a given population into variance that is attributable to genetic influences (G) that will include additive (A) and nonadditive (D) contributions, shared or common environment (C) and nonshared environmental (E) factors. The nonshared environment component will also include measurement error and contributions from stochastic events. Traditionally, twin studies cannot simultaneously test C and D and are much better powered to detect G than C. Twin studies can be extended to include other types of relatives; for example, biological siblings, half siblings, and step siblings.

The proportion of total phenotypic variation explained by genetic factors is known as heritability (h^2), a quantity about which there is a good deal of misunderstanding (Tenesa & Haley, 2013). Heritability is a population attribute; it refers to differences *between* people from a given population. For example, the high heritability estimates (80–90% in some studies) for autism and ADHD do not mean that 80–90% of an individual's ADHD or autism is explained by genes. For example, if a population was universally exposed to the critical environmental risks, then there would be very little environmental variance and heritability estimates would accordingly be high.

The disparity between high h^2 estimates for many common psychiatric conditions and the amount of variance captured via genome-wide association studies has been the subject of much discussion (Lee *et al.*, 2011). There are many potential explanations for this so-called "missing heritability." Potential factors include the contribution of rare variation, which may not be detected in current studies of common variation; the likely importance of nonadditive genetic influences including epistasis (gene–gene interaction); the contribution of environmental risks (gene–environment correlation and interaction) (discussed later), and an overestimation of heritability from twin studies.

The strength of the twin design is that it can be used for multiple purposes beyond simply testing whether a disorder or trait is heritable. For example, many forms of psychopathology can be usefully viewed as dimensions as well as categorical disorders. Twin findings further suggested that genetic risks for many psychiatric disorders influence variation in trait measures of these phenotypes in the general population and that these operate across the spectrum of severity (Rutter, 2011; Thapar *et al.*, 2013).

Twin studies have also consistently shown that genetic risks operate beyond diagnostic boundaries and across diagnostic categories. In this case, recent molecular genetic findings are in keeping with this observation. The same common and rare genetic risk variants or sets of variants cross diagnostic boundaries (Cross-Disorder Group of the Psychiatric Genomics *et al.*, 2013). For example, twin studies have found that shared genetic contributions explain most of the comorbidity between different psychiatric disorders, while nonshared environmental influences appear to be more disorder specific (Lahey *et al.*, 2011).

A final major strength of twin study and other genetically informative designs is that by providing an indirect measure of genetic contributions, it becomes possible to test the effects of environment independent of associations that arise through genes. The uses of genetically informative designs in testing causal hypotheses in relation to environmental risks are described in Chapter 12.

It is nonetheless important to understand some of the limitations of twin designs. These include a reliance on MZ twins being genetically identical when there are differences between them, including post zygotic mutations and epigenetic variation. As a result, discordant MZ twin pairs are now being utilized not only to identify if measured aspects of environment contribute to psychopathology (see Chapter 12) but also to test whether biological markers such as epigenetic signatures distinguish affected and unaffected twins (van Dongen *et al.*, 2012). Another key assumption is that MZ and DZ twins share environment to the same extent. MZ twins likely have greater sharing of intrauterine influences and many later environmental risks will be shaped by genetically influenced dispositions, thereby also serving to inflate heritability estimates. For example, MZ twin similarity would be inflated through greater sharing of prenatal influences.

Adoption studies

In adoption study designs, the contribution of genetic factors is inferred when individuals show greater phenotypic similarity to their biological relatives than with their unrelated adoptive relatives. There have been three main variants of this design. First, there are the studies of adopted away offspring of parents with a psychiatric disorder. Early studies of this type showed a strong genetic contribution to schizophrenia that extended to risks for a broader "schizophrenia spectrum" (Tienari *et al.*, 2003). The second design focuses on individuals who have been adopted away and examining the rates of disorder in adoptive and biological relatives. These types of design have, for example, highlighted an important genetic contribution to ADHD (Thapar *et al.*, 2013) and shown that exposure to adoptive maternal depression contributes to adolescent depression (Tully *et al.*, 2008). Finally, cross-fostering designs are based on comparing rates of psychopathology in high genetic risk individuals who have been adopted away into low environmental risk families against the rates observed in (1) adoptees at low genetic risk, low adoptive environmental risk and (2) those at high genetic risk and who are exposed to high environmental adversity. Such studies are rare but have highlighted, for example, that while genetic liability is needed to manifest petty criminality, the risk effects are greatly magnified in those placed in adoptive homes with low social status (Cloninger *et al.*, 1982). Adoption studies provide a useful means of demonstrating gene-environment interaction that we discuss later.

Adoption studies also have their own set of assumptions and limitations (see Chapter 12). For example, the design is based on adoptive placements being nonselective. Adopted away children at genetic risk will likely also have been exposed to prenatal adversities influenced by biological maternal genetic dispositions and unless adoption takes place at birth, early environmental adversity provided by biological parents will also inflate phenotype similarities between biological relatives. Adoptive families tend to come from more advantaged backgrounds, thereby restricting the range of environmental exposures (Stoolmiller, 1999) and potentially reducing power to detect environmental contributions.

Approaches to gene discovery

Parametric linkage analysis

For many decades, parametric linkage has been the gold standard approach to gene discovery in disorders reflecting Mendelian inheritance, that is, an essentially one-to-one relationship between a particular mutation and a given disease or syndrome. Linkage is based on the idea that the position within the genome of an unknown disease mutation may be found by examining the transmission of known genetic variations (or markers) in an affected family or group of families. If the unknown disease-causing variant is sufficiently close to a known marker, these variants will very frequently be inherited

together despite homologous recombination and are thus termed "linked."

Parametric linkage involves *a priori* hypotheses about the mode of inheritance (e.g., dominant, recessive, X-linked), the frequency of the disease mutation in the population (typically, very rare), the penetrance of mutation (i.e., what proportion of those with the mutation show the disease), and the frequency of phenocopies (i.e., what proportion of affected individuals show the disease who do not carry the sought after mutation). The genome is then examined for the inheritance of known markers within selected families and the probability of seeing the observed pattern of inheritance for each of these known markers under the model of linkage is compared to the probability of seeing the observed pattern under the null hypothesis. If a marker or markers that show a high probability of being linked are identified, this region or these regions of the genome are examined in more detail—using more markers to fine map the "linkage interval" or, more recently, via exome or genome sequencing—with the ultimate aim of identifying the rare disease-causing mutation.

Many mental disorders were originally thought likely to reflect Mendelian inheritance of one or a small number of disease genes. However, for the most part, psychiatric syndromes have subsequently been found to be the result of complex inheritance, involving many genes—both within the individual, as well as within the population—the contribution of nongenetic factors, and demonstrating a probabilistic relationship between having a mutation and any given phenotypic outcome. These characteristics have limited the usefulness of parametric linkage in psychiatric genetics.

However, a so-called "outlier" approach to gene discovery is based on the hypothesis that even within a genetically complex disorder or syndrome, there will be examples of simpler inheritance. Several of the earliest successes in psychiatric genetics involved taking just such an approach, including the identification of mutations in the gene *Neurologin 4X* in autism spectrum disorder (ASD) (Jamain *et al.*, 2003). More recent applications of this approach have identified recessive mutations contributing to neurodevelopmental disorders (Morrow *et al.*, 2008).

Common variant / candidate gene studies

The combination of the failure of broader efforts at applying Mendelian approaches to psychiatric illness; a reconceptualization of psychiatric disorders as complex and likely involving common polymorphisms; and the relatively low cost of genotyping assays all led to a dramatic rise in candidate gene approaches. Initially, this involved identifying one or a small number of common variations or SNPs present in one or a small number of specific genes of interest. These variations were most often selected on the basis of biological plausibility and then assessed in some version of a case-control design to determine if the frequency of a specific variant (allele) was greater in affected individuals.

Such approaches were initially very attractive. From a conceptual standpoint, there is an understandable draw toward

hypothesis-driven experiments. Moreover, the logistics of mounting a candidate gene association study were comparatively straightforward. Investigators were able to recruit tens to hundreds of affected individuals at one or a small number of sites. Genotyping assays were relatively inexpensive, and less computationally intensive than doing whole genome linkage analyses. Finally, there were a large number of biologically attractive candidates to evaluate, including multiple genes encoding components of neurotransmitter systems.

These investigations came to occupy a very large proportion of the psychiatric genetics literature. However, they suffered from a general lack of reproducibility (Hirschhorn *et al.*, 2002). The causes for these inconsistencies initially led to considerable debate. However, with the emergence of high-throughput parallel genotyping assays and the rise of so-called genome-wide association studies (GWAS), many of the sources for these early difficulties became readily apparent (Altshuler *et al.*, 2008).

Genome-wide association studies

GWAS focus on the contribution of common variation to common psychiatric disorders but take a hypothesis-free approach to gene discovery (Risch & Merikangas, 1996). The ability to do so was conditioned on the development of microarrays that allowed for the inexpensive and rapid detection of common polymorphisms at every gene in the genome. It became apparent that it would be necessary to evaluate multiple variations at any gene of interest to determine with confidence whether it played a role in a given phenotype. Consequently, the development of arrays capable of testing initially tens of thousands and now millions of SNPs simultaneously resulted in the ability to conduct a genome-wide, as opposed to a candidate gene, association study.

As this technology was employed, it became clear that the approach was capable of yielding highly reproducible results (Edwards *et al.*, 2005; Haines *et al.*, 2005; Klein *et al.*, 2005). Accordingly, in retrospect, the difficulties with prior candidate gene approaches became clear: first, the effect sizes hypothesized for most candidate gene studies were an order of magnitude or more higher than what eventually has been found to obtain for common variants; second, the likelihood of selecting, *a priori*, the correct variant(s) in the correct gene(s) turned out to be very low. Finally, any case and control cohort in GWAS or candidate gene association studies need to be matched for ancestral origin, a key confound in genetic association studies. It took the sequencing of the human genome and the development of high-throughput tools to reveal how sensitive case-control studies could be to occult differences in ancestry, and to provide the means to correct for this confound (Altshuler *et al.*, 2008).

The use of the GWAS approach, coupled with rigorous statistical thresholds that take into account the hundreds of thousands of comparisons being conducted simultaneously, has led to a spate of reliable and reproducible findings in psychiatric conditions, including schizophrenia and bipolar disorder. At the time of writing, for schizophrenia, 108 loci have been

identified through GWAS but this has required around 40,000 cases and 40,000 controls (Schizophrenia Working Group of the Psychiatric Genomics Consortium, 2014). Several general observations from GWAS are notable: first, a substantial portion of the variation that has been found to be associated with disease risk maps to intergenic regions. This observation may be explained, at least in part, by a relative overrepresentation of noncoding common alleles on genotyping assays. However, the findings also raise the prospect of a prominent role for gene regulation in disease risk. Second, as noted earlier, the effect sizes for common alleles have been much smaller than anticipated. Associated loci rarely exceed a twofold increase in risk, and typically fall below a 50% increase.

These findings provide important data with regard to interpreting genetic association studies. As noted, the small effects, in retrospect, suggest that the majority of early candidate gene and candidate gene-environment interaction studies (see later) were dramatically under powered. In addition, the absence of statistically significant and reproducible GWAS results for some common complex psychiatric disorders, such as autism or Tourette's disorder, may still say less about the types of variation that contribute to disease risk and instead highlight the need to develop larger cohorts for these conditions; ones that rival those studied in schizophrenia.

Cytogenetics

The earliest efforts at rare variant discovery rested on either parametric linkage analysis, as described previously, or traditional cytogenetics. The study of chromosomal abnormalities has had considerable impact on psychiatric genetics. For example, the cloning of the fragile X gene, now appreciated to be associated with both autism as well as intellectual disability, was made possible by the observation of a chromosomal fragile site (Sutherland, 1977). Similarly Neurologin 4X, a gene associated with autism risk, was discovered initially through the investigation of genomic intervals disrupted by chromosomal rearrangements (Jamain *et al.*, 2003).

Such investigations initially involved the light microscope and subsequently made use of fluorescent probes to increase resolution, an approach known broadly as molecular cytogenetics. However, these methods were largely restricted to fine mapping either one or a very small number of targeted chromosomal regions.

Copy number variation analysis

This limitation was eliminated, however, by the development of microarray technology and the identification of CNVs as part of typical human genetic variation. CNVs are now known to contribute risk of autism, schizophrenia, ADHD, and a range of other neurodevelopmental syndromes (Malhotra *et al.*, 2011).

It also became clear that copy number changes were not distributed randomly across the genome, but instead accumulated at particular regions in affected individuals, providing an avenue to identify specific chromosomal intervals, and in some

cases specific genes, associated with disease (Kumar *et al.*, 2008; Marshall *et al.*, 2008; Weiss *et al.*, 2008).

Some early CNV studies focused on *de novo* copy number variation and so-called simplex families with only one clearly affected proband. These were based on the hypothesis that the apparently “spontaneous” emergence of a neurodevelopmental or neuropsychiatric phenotype in a family could be accounted for in some cases by a new mutation. This hypothesis was further supported by the reasoning that mutations carrying large effects, particularly for early-onset disorders, would be subject to “purifying” natural selection and would tend to be removed from the genome over generations (Figure 24.3). Indeed, for disorders in which CNVs have been found to play a role, the identification of *de novo* mutation has proved to be a particularly powerful means to identify associated loci, and overall these new mutations have been found to carry larger effects than either common or rare transmitted variation contributing to common psychiatric disorders (Malhotra & Sebat, 2012).

Next-generation sequencing

The rapid evolution of DNA sequencing over the past few years has now made possible the identification of rare and *de novo* mutations at single base resolution, across substantial portions of the genome. Two study designs have so far predominated, both focusing on rare mutations in exomes, either in traditional case-control cohorts or via the study of simplex families looking for *de novo* mutation. Both types of studies have evaluated the overall burden of mutations in comparison groups as well as the distribution of these mutations, looking for “recurrence.” This refers to the identification of a *de novo* mutation in the same gene, as opposed to observing the precisely identical mutation.

Early applications have been quite productive. For example, in autism, the identification of recurrent *de novo* mutations that result in a loss of protein function has led to the identification of multiple associated genes (O’Roak *et al.*, 2011; Iossifov *et al.*, 2012; Neale *et al.*, 2012; O’Roak *et al.*, 2012; Sanders *et al.*, 2012).

An additional interesting observation (Iossifov *et al.* 2012; Neale *et al.*, 2012; O’Roak *et al.*, 2012; Sanders *et al.*, 2012; Kong *et al.*, 2012) has been that the rate of *de novo* single base mutations is strongly correlated with paternal age. This finding represents an important example, at the molecular level, of gene-environment interplay. In addition, it suggests that there are likely to be other environmental inputs that contribute to or protect against *de novo* mutation and consequently could influence the prevalence and population distribution of autism and other neurodevelopmental and psychiatric disorders.

Gene × environment interplay

Findings generated by traditional genetic epidemiological studies of psychopathology highlight that the effects of genes and environment are interdependent (see Chapter 23; Rutter, 2012). Environmental risks that are of the type most relevant to psychiatric disorder are not randomly allocated; they are shaped by genetically influenced dispositions and behaviors.

This is known as gene-environment correlation. The phenotypic manifestations of genetic liability captured indirectly through traditional studies or assessed at a molecular level depend on exposure to particular environmental conditions. Gene-environment interaction ($G \times E$) is a well-established phenomenon in animal and plant genetics but has created more controversy in psychiatry. Whilst $G \times E$ has been more difficult to consistently detect at a molecular level in human studies, its importance is well established and undisputed for less complex organisms (Lehner, 2013).

Gene-environment correlation

Most types of environmental risks that have been considered important in relation to psychopathology, for example, adverse life events and quality of family relationships, have been found to be familial and heritable. This is unsurprising given that exposure to and perception of environmental risks are affected by genetically influenced attributes of parent and/or child (see Chapter 12). The correlation between parental genotype and environmental risks is known as passive gene-environment correlation. For example, a parent who has a genetic disposition toward being socially anxious, not only transmits risk genes to offspring but might, for example, also avoid situations that reduce socialization experiences for their children and magnify similar traits in their offspring. Passive gene-environment correlation effects (when postnatal in origin) are removed in adoption study designs. Genetically influenced attributes of children are also important as they shape environmental exposures, not only by seeking out experiences but also by evoking responses in others. These situations are considered as active and evocative gene-environment correlation. Adoption studies, for example, have found that this is important in relation to harsh discipline and negative parenting in adoptive parents of children who are genetically predisposed to being antisocial (as indexed by an antisocial biological parent). These environmental risks appear to be evoked by the children’s behavior (Ge *et al.*, 1996).

There is now a wealth of literature highlighting that risk genes and environments often co-occur and show interdependence in this way.

Gene-environment interaction

In this chapter we consider $G \times E$ conceptually rather than as a statistical term. This phenomenon is where genetic predisposition, or a particular mutation or gene, only has risk effects or has much stronger risk effects in the presence of an environmental factor. Such a situation is much more easily assessed in experimental studies of organisms where the genetic background and environmental exposures are controlled by the researcher.

The situation is complicated in humans because we have to focus on phenotypes that are difficult to measure and complex in origin. Multiple genes and environmental risks are involved. Another issue is that whilst gene-environment interaction is a conceptual term, in observational studies, we rely on assessing statistical interaction that is not the same as biological

interaction but does provide a start point (Rutter *et al.*, 2009). Also, it is impossible to exactly reproduce the same types of sample and control for multiple environmental exposures and genetic backgrounds.

Nevertheless, traditional genetic epidemiological studies have consistently highlighted that environmental risks do not have the same effects on all and that genetic and environmental risks work together. While family and twin studies have tested for gene–environment interaction ($G \times E$), adoption studies have afforded an especially powerful means of investigating $G \times E$. Such studies have found not only are those at higher genetic risk more likely to be exposed to environmental risks but the effects of environmental adversity appear to be stronger in genetically predisposed individuals. For example, family and twin studies of adults and adolescents have shown that the risk effects of life events are increased in those at increased genetic and familial risk of depression (Kendler *et al.*, 1995; Silberg *et al.*, 2001). As we have already discussed, adoption studies find that those at genetic risk of antisocial behavior appear to be much more sensitive to adverse rearing adoptive environments. Similar findings have been shown in adoption studies of schizophrenia.

As already mentioned, gene–environment interactions have been widely observed in organisms that are less complex than humans and other primates (Lehner, 2013). Thus, it is well recognized that the effect of a genetic mutation on a phenotype is influenced by exposure to a specific environmental condition or a specific environmental trigger (e.g., diet, exposure to pathogen). The environment can also influence interactions between genes and alter the phenotypic effect of mutations by changing other biological processes, for example, by altering proteins (Lehner, 2013).

However, while the rationale for studying $G \times E$ interactions is well established, human molecular genetic studies of gene–environment interaction have attracted controversy, largely due to concerns about the reliance on candidate gene strategies and the attendant confounds and limitations already noted. In addition, the challenge with regard to the identification and utilization of good measures of environment has also been highlighted (Rutter *et al.*, 2009; Caspi *et al.*, 2010).

A prime example of this controversy is a very highly cited finding regarding the risk for a depression based on the cross product of earlier experience and genotype (Caspi *et al.*, 2002). Specifically, a functional variant in the promoter region of the serotonin transporter gene was found to be associated with depression in the presence of life events. The findings have since been replicated in multiple studies, partly replicated and also nonreplicated by many. An initial meta-analysis found no evidence for association across studies (Risch *et al.*, 2009; Rutter *et al.*, 2009). However, a subsequent meta-analysis found significant evidence of gene–environment interaction and suggested that the key risk stemmed from exposure to early maltreatment (Karg *et al.*, 2011). Other studies have investigated alternative stress-related and behavioral phenotypes (Caspi *et al.*, 2010).

The back and forth regarding this study underscores the difficulties that have emerged as scepticism regarding candidate gene methodology has mounted. Indeed, the key issue is not whether this or other prior findings from candidate gene studies are “correct,” but rather what types of evidence would be required at this point to confirm or refute these associations. Different investigators are likely to provide divergent answers. However, in general, it is reasonable to suspect that, just as GWAS has become the gold standard for identifying common variants contributing to common disorders, the rigorous application of genome-wide approaches will be an essential contributor to reaching a consensus on the interaction between common variation and environmental factors. The same issues are likely to apply to investigations of “differential susceptibility,” whereby some individuals are more susceptible not only to environmental risks but also to potentially beneficial environmental conditions including those provided through intervention (Pluess & Belsky, 2013).

Pharmacogenetic/pharmacogenomics

All clinicians are familiar with the observation that individuals show considerable variation in their responses to pharmacological agents with respect to efficacy and side effects. Pharmacogenetic investigations aim to identify the genetic contributions to this variation in drug response that are a form of gene–environment interaction. There has been enormous interest in the idea of personalized medicine across the whole of medicine, whereby drug treatments are tailored to an individual according to biological and clinical profiles.

To date, most pharmacogenetic studies in psychiatry have involved candidate genes in neurotransmitter systems thought to be targeted by the pharmacological agent and involved in generating side effects (e.g., weight gain with atypical antipsychotic medication) or therapeutic responses. No strong, consistent findings have emerged. Other studies have dealt with genetic variation in pharmacokinetics that deals with drug metabolism; for example “slow” and “ultra-rapid” metabolizers of drugs metabolized by the enzyme CYP2D6. Consistent findings have so far been limited in psychiatry and one relevant issue here is that the efficacy of most psychotropic medications is not closely related to circulating plasma levels (Malhotra *et al.*, 2012).

For pharmacogenetics and other genetic studies of interventions to have clinical impact, genetic risks must have strong predictive value and replicate well across different populations. While it is theoretically possible that the genetic variants involved in responses to treatment and side effects have larger effect sizes than those that contribute to psychiatric phenotypes, there is little evidence so far to support this view.

Intermediate phenotypes

Investigating how genetic factors associated with psychiatric disorder might exert their risk effects can be conducted at

many different levels. These span from the cellular and biological to encompass investigations of brain structure and function. Intermediate phenotypes such as cognitive and imaging measures have been viewed by some to represent biological substrates that might lie closer to genes than psychiatric diagnoses. For example in general medicine, cholesterol levels can be considered as an intermediate phenotype that lies along a causal risk pathway to ischemic heart disease. It is however difficult in psychiatry to determine if a hypothesized intermediate phenotype truly lies along a causal pathway. Such measures could, for example, simply reflect another aspect of the psychiatric disorder in question. Also, genetic variants have multiple pleiotropic risk effects on different brain/behavioral phenotypes. Genetic imaging and cognitive studies can nevertheless potentially provide some valuable insights into potential mechanisms and neural substrates that are influenced by genetic risks but that cross diagnostic boundaries. Intermediate phenotypes most commonly studied in psychiatry have involved cognitive and structural and functional imaging measures. Traditional genetic epidemiological studies have shown that most of these measures are heritable and for many, shared genetic influences contribute to their covariation or correlation with specific psychiatric disorders. Nevertheless, like psychiatric disorders, these sorts of phenotypes are still genetically complex and so far, there is little to suggest that their genetic architectures are simpler than those underlying psychiatric disorders. For example, recent very large-scale genetic studies of brain structure highlight that multiple genetic variants of very small effect size appear to contribute to phenotypic variation, appearing nearly identical to the types of findings seen in GWAS studies of categorical diagnoses.

Findings on how single genetic risk variants that have been found to be associated with a psychiatric phenotype relate to different neural measures are still at an early stage in terms of robust replications. While earlier studies utilized candidate genes that were not robustly associated with psychiatric disorder, more recent investigations are focusing on more strongly replicated genetic findings. For example, imaging has suggested that *ZNF804A*, a gene now known to be associated with schizophrenia, might be implicated in disrupting brain connectivity (Esslinger *et al.*, 2009).

Other studies are beginning to test the impact of common and rare risk variants on neural circuitry not only in humans but also using animal models. It is likely that the emergence of new techniques that enable improved characterization of neural circuitry and architecture (e.g., Chung & Deisseroth, 2013) (see Chapters 10 and 11) will be used in the future to further investigate mechanisms that mediate genetic risk effects.

Genetic testing

We conclude this chapter by considering clinical implications with regard to genetic testing and counseling. In most instances, the estimated recurrence rate of any psychiatric disorder has had

to be estimated from family studies. This of course does not provide a risk estimate that is individually tailored. Molecular testing of individual and composite common genetic risk variants has so far been of limited predictive utility.

In contrast, it has long been accepted that when a rare chromosomal anomaly or syndrome is clinically suspected, the effects are more predictable and cytogenetic testing and/or targeted molecular investigation of that syndrome (e.g., tuberous sclerosis) is indicated. In the past few years, genome-wide chromosomal microarray clinical investigations have become routinely available in many countries. Potential benefits of testing individuals and their relatives for such mutations include an enhanced understanding of how the disorder has arisen, access to information and support groups for those with certain types of CNVs (e.g., 22q11 microdeletion), early recognition and treatment of medical conditions when known to be a feature of the mutation, and more individually tailored risk prediction estimates for those who wish. However, there are complexities with regard to accurately interpreting risks because CNVs are so highly pleiotropic and probabilistic in their effects. Moreover, there are multiple ethical issues that arise from identifying a mutation including potential stigma, discrimination, and family conflict; these require careful consideration and expert counseling (Gershon & Alliey-Rodriguez, 2013).

So, what does the child and adolescent mental health clinician need to do? We recommend that clinicians consult their local clinical genetics service and be familiar with national and local guidelines as there is considerable variation currently in recommendations for testing as well as the investigations and counseling resources available. Also, rapid changes in technology, its cost, and emergent findings mean that guidelines will inevitably change. For example, the American College of Medical Genetics and Genomics guideline revisions in 2013 (Schaefer *et al.*, 2013) highlight that for ASD, the diagnostic yield has risen from 6–10% a few years ago, to 30–40% because of advances in testing technology. They recommend that genetic testing should be discussed with all patients and families with ASDs. The current UK National Institute for Health and Care Excellence (NICE) guidelines on autism (see Chapter 51) suggest that genetic testing should only be routinely performed on those with dysmorphic features and/or intellectual disability but acknowledge technology is rapidly changing.

Overall, referral to clinical genetics services for investigation and counseling would likely be most appropriate for children with ID and for complex presentations of ASD, ADHD, or schizophrenia (i.e., accompanied by ID (intellectual disability), dysmorphic features, or a medical condition). Additional selection criteria will depend not only on genetic discoveries but also on consideration of how well placed local clinical genetics services are in interpreting risks and providing appropriate counseling. Moreover, these processes require a deeper understanding of the ethical implications, sensible use of limited resources, and consideration of clinical utility.

Summary: recent findings and changing conceptions

There is now the appreciation that a wide range of genetic variation can contribute to the same psychiatric phenotype (Figure 24.3). Moreover, it seems likely that the distribution of these classes of genetic variation is not uniform across all common psychiatric conditions. These observations suggest that the future success of gene discovery efforts will reflect a cross product of methodology, sufficient sample size, and the nature and distribution of the genetic risk for that phenotype.

A recent, conceptually challenging observation from both common and rare variant studies has been the wide range of phenotypic outcomes that have been related to the identical variation. Indeed, the means by which the identical variation may result in outcomes with very different natural histories and treatment responses is emerging as a major preoccupation. Perhaps the most important question emerging from these studies is why a genetic variation with such widely divergent outcomes will sometimes lead to no psychiatric phenotype at all.

Another notable observation is the extraordinary degree of genetic heterogeneity of psychiatric disorders. Estimates for genes contributing to ASD range from hundreds to as high as a thousand (Levy *et al.*, 2011; Sanders *et al.*, 2011; Iossifov *et al.*, 2012; Sanders *et al.*, 2012). So far, more than 100 common variant loci have been found to be associated with schizophrenia, with evidence of considerably more to be discovered (Lee *et al.*, 2012). These findings, along with the observations already noted, in which a single mutation may lead to a wide range of phenotypic outcomes, suggest that the study of individual mutations, one at a time, may not be sufficient to identify molecular mechanisms specifically relevant to a given disorder. Indeed, it is likely that it will be important to understand how, when, and where during brain development, multiple distinct mutations contributing to a given disorder converge (State & Sestan, 2012). Consequently, the application of systems biological approaches is likely to be increasingly relevant to making the transition for gene identification to the illumination of mechanisms of disease.

Fortunately, the tools necessary to make sense of findings are evolving as rapidly as the genomic tools that have made these discoveries possible. Traditional model systems, such as rodents, will continue to play a central role in linking genes to brain and behavior and the ability to manipulate these animal models is expanding dramatically (see Chapter 12). There are now a wide array of methods that allow for modeling temporally and spatially defined genetic alterations, ranging from conditional knock-outs to viral vectors to optogenetics. These advances have led to an unprecedented ability to manipulate and study specific neuronal cells and circuits. Moreover, the ability in model systems to recapitulate or correct specific mutations found in humans is being accelerated by the development of technologies that allow for the rapid introduction of highly specific mutations into the genome (Gaj *et al.*, 2013).

An equally exciting recent development facilitating the translation of genomic findings in psychiatry into an understanding of molecular mechanisms has been the evolution of induced pluripotent stem cells (iPSCs). iPSCs allow for the creation of specific neuronal cell types from a range of accessible human cells including skin fibroblasts, blood lymphocytes, and hair follicles. The attendant possibilities are numerous, from creating a neuronal cell from a patient with a given mutation and then correcting that mutation, to generating a series of disease-related mutations in a well-characterized so-called isogenic iPSC line, to implanting human neuronal iPSC lines into other model organisms to detect and study non-cell-autonomous effects.

Reliable and systematic methods to detect genetic risk factors for common psychiatric disorders are establishing a critically important foundation for the next generation of studies. Along with parallel advances in neurobiology, systems biology, computational sciences, and genetic epidemiology, the field is now poised to begin to elaborate the molecular-, cellular-, and circuit-level mechanisms of complex psychiatric illness and to clarify the complex interplay of environmental and genetic risk factors.

CHAPTER 25

Epigenetics and the developmental origins of vulnerability for mental disorders

Michael J. Meaney^{1,2} and Kieran J. O'Donnell¹

¹Ludmer Centre for Neuroinformatics and Mental Health, Douglas Mental Health University Institute, McGill University, Montreal, Canada

²Singapore Institute of Clinical Sciences, A*STAR, Brenner Centre for Molecular Medicine, Singapore

There are profound developmental origins for individual differences in mental health that extend over the lifespan. Maternal perinatal anxiety/depression, low socioeconomic status (SES) and child maltreatment, including emotional and physical neglect and abuse, all predict poor child and adolescent mental health. Importantly, child maltreatment not only predicts the risk for multiple mental disorders, but at least in the case of depression, also the severity and treatment response (Nanni *et al.*, 2012).

An obvious question concerns the mechanism by which the effects of the early environment, including variations in parent–offspring interactions, are embedded in the molecular machinery that regulates genomic transcription (see Chapter 24). In this chapter we examine the evidence for the environmental epigenetics hypothesis, which proposes that the sustained effects of environmental conditions on gene expression are mediated by effects on the epigenetic mechanisms that regulate the transcriptional machinery. We also discuss the current status of translational research that examines the role of epigenetics in the context of the developmental origins of vulnerability for mental disorders in humans.

Parental influences

Studies with a remarkable range of species reveal profound parental influences on the phenotype of the offspring. Within evolutionary biology and ecology such parental effects are defined as instances in which the phenotype of the offspring is affected by that of the parent, independent of genetic inheritance. Such effects are considered as a primary mechanism for phenotypic plasticity (i.e., variation in genotype–phenotype relations). There are also examples of parental mediation where environment effects on the phenotype of the developing animals are directly regulated by parental signals. Such parentally

induced variation in phenotype is considered to be adaptive (i.e., when the resulting phenotype enhances survival and reproduction). In the meadow vole, offspring growth, fur thickness and sexual maturation are influenced by the length of daylight experienced by the mother during the perinatal period, preparing her offspring for the approaching winter (Lee & Zucker, 1988; Lee, 1993). In the red squirrel, increased population density associates with greater offspring weight gain in the early postnatal period, which may enhance survival beyond the first year of life (Dantzer *et al.*, 2013). Similarly, in the desert locust, maternal lifetime exposure to increased population density also has profound effects on the phenotype of her offspring. In areas of low population density, desert locusts produce cryptic, solitary offspring. In contrast, progeny from females exposed to high population density are more gregarious and demonstrate migratory behaviors, easing competition for resources in the local environment (Saiful Islam *et al.*, 1994). Collectively, these examples serve to demonstrate the importance of environment-dependent parental signaling for offspring development, fitness and survival. The question arises as to the extent and mode of transmission of parental effects in humans, and their relevance for child development and vulnerability for later mental disorder.

Studies of children born to Holocaust survivors illustrate how early environmental adversity confers vulnerability for later mental health disorder. Yehuda and colleagues (2008) show an increased risk of posttraumatic stress disorder (PTSD) in children born to Holocaust survivors as a function of maternal, rather than paternal, PTSD. This group has also shown altered neuroendocrine function in children of Holocaust survivors, again more strongly associated with maternal PTSD, and most pronounced in children born soon after the Holocaust, suggesting some specificity for maternally mediated effects. Similar effects of maternal, rather than paternal, prenatal anxiety

and depression on child emotional/ behavioral development (O'Donnell *et al.*, 2013) and neuroendocrine function have also been reported (O'Donnell *et al.*, 2013) (see Chapter 5). Thus, the challenge includes not only that of understanding the immediate effects of the environment on parent–offspring interactions but also the persistence of such environmental influences on offspring development.

The critical assumptions for this parental signaling hypothesis are that (1) there is a systematic relation between the quality of the environment and the nature of the parental signal, (2) that the offspring have evolved the necessary mechanisms to respond to the parental signal, and (3) that the parental signal initiates the intracellular systems that reliably produce and maintain the specific phenotypic variation. Likewise, natural selection should favor offspring that are better able to decode accurately parental signals as a “forecast” of the conditions that lie ahead (see Hinde, 1986). Psychologists would suggest that the same argument extends to parental sensitivity (i.e., the ability to decode the signals from the offspring). We argue that the parental signaling implicit in the study of parental effects is widely apparent in studies of child development and that epigenetic mechanisms contribute to the biological embedding of parental signals. Here we introduce the topic of epigenetics and use examples from our studies in rodents to illustrate how epigenetic modifications to DNA can have lasting effects on gene transcription/expression and the phenotype of the organism. This is followed by a review of clinical epigenetic studies of relevance to child development and vulnerability to mental disorders. While this chapter focuses predominately on maternal care, and more broadly, the effects of early adversity, on epigenetic processes, it should be noted that there are other factors that may influence the epigenome across the lifespan. Examples include, but are not limited to, smoking and environmental toxins, psychotropic drugs, UV exposure and radiation, as well as several disease processes including cancer.

Epigenetics

Epigenetics, stemming from the Greek “*epi*” meaning “upon” and “*genetics*,” refers to a series of chemical modifications to chromatin that regulate genomic transcription. Indeed, epigenetics has become largely synonymous with the study of transcriptional regulation, that is, the degree to which a gene is expressed or repressed.

For reasons of graphic simplicity, we often describe the organization of a gene as if the DNA were a linear molecule to which transcription factors (the proteins that read the DNA sequence and initiate gene expression) gain unimpeded access. The reality of protein–DNA interactions is very different. Figure 25.1 presents the classic crystallographic analysis of the organization of DNA (Luger *et al.*, 1997). DNA is commonly organized in a form that resembles beads lying along a string (Figure 25.2). The beads are nucleosomes comprised of ~146 base pairs wrapped around a core of histone proteins (Turner, 2001). The histones

Figure 25.1 Nucleosome core particle.

Ribbon traces for the 146-bp DNA (grey double helix) wrapped around a single nucleosome consisting of eight histone proteins, with two copies of H2A (yellow), H2B (red), H3 (blue) and H4 (green). Histone tails, the sites of functional post-translational modifications, can be seen extending from the nucleosome core. (Source: www.commons.wikimedia.org/wiki/File:Nucleosome_1KX5_colour_coded.png).

and DNA together are referred to as chromatin; the nucleosome is the organization of chromatin.

Under normal conditions there is a tight physical relationship between the histone proteins and the accompanying DNA, resulting in a closed nucleosome configuration. This restrictive configuration is maintained, in part, by electrostatic bonds between the positively charged histones and the negatively charged DNA. The closed configuration impedes transcription factor binding and is associated with a reduced level of gene expression (Figure 25.2). Epigenetic modifications essentially favor a closed or open state of chromatin that either increases or decreases the ability of transcription factors to access regulatory sites on the DNA, which control gene transcription.

Chromatin modifications

The dynamic alteration of chromatin structure is achieved in part through covalent modifications to the histone proteins at the amino acids that form the histone protein tails extending out from the nucleosome (Figures 25.1 and 25.2). There are several examples of such modifications including, but not limited to, acetylation, phosphorylation, methylation and ubiquitylation (see Maze *et al.*, 2013). These modifications are achieved through a series of enzymes that bind to the histone tails and modify the local chemical properties of specific amino acids (Grunstein, 1997; Jenuwein & Allis, 2001). For example, the enzyme histone

Figure 25.2 Chromatin dynamics and gene transcription.

DNA within a cell's nucleus coiled around histone proteins resembling beads on a string (upper panel: black lines/light blue circles). Increased repressive modifications to histone tails (red circles) and DNA methylation (dark blue circles) promote a closed conformation associated with gene inactivation (heterochromatin; lower left panel). Histone acetylation (green circles) and DNA demethylation associate with an open chromatin configuration, increased transcription factor binding and active gene transcription (euchromatin; lower right panel). DNMTs = DNA methyltransferases, HDACs = histone deacetylases.

acetyltransferase “transfers” an acetyl group onto specific lysine amino acids on the histone tails. The addition of the acetyl group diminishes the positive charge, loosening the relation between the histones and DNA, opening the chromatin and improving the ability of transcription factors to access DNA sites. Thus, histone acetylation at specific lysine sites is commonly associated with active gene transcription. Nucleosomes in this open, permissive state are termed *euchromatin* (Figure 25.2).

The functional antagonists of the histone acetyltransferases are a class of enzymes known as histone deacetylases (HDACs). These enzymes remove acetyl groups and prevent further acetylation, thus maintaining a closed chromatin structure, decreasing transcription factor and gene expression. Both the acetylation and deacetylation of histones is a dynamic process that is regulated by environmental signals. Additional histone modifications, notably histone methylation, act less directly. Methylation can occur at multiple amino acid sites in the histone tails and then attracts protein complexes that mediate either the closure or opening of chromatin. Methylation or demethylation at individual sites is catalyzed by specific enzymes. Stability is an important feature of histone methylation; unlike acetylation, methylation marks can persist and have been shown to directly mediate the stable influence of environmental signals on gene transcription (Sun *et al.*, 2013).

DNA methylation

Another level of regulation occurs directly on the DNA. Indeed, the classic epigenetic alteration is that of DNA methylation, which involves the addition of a methyl group (CH_3) onto cytosines predominately bound to guanines (CpGs) in the DNA (Razin & Riggs, 1980; Bird, 1986). More recently non-CG methylation, occurring on cytosines usually followed by an adenine base, has been identified. Both CpG and non-CG methylation show dynamic change across human brain development and are relevant for the specification of neurons and glia (Lister *et al.*, 2013). As very little is currently known about non-CG methylation and mental health outcomes, this chapter focuses on CpG DNA methylation.

DNA methylation in the gene promoter, the regulatory region associated with the initiation of transcription, is typically associated with transcriptional repression. The repressive effect of DNA methylation on gene transcription appears to be mediated in one of two ways. First, wide swaths of densely methylated DNA preclude transcription factor binding to DNA sites, thus silencing transcription. The second manner is subtler, and probably far more prevalent in regions with more dynamic variations in gene transcription, such as the brain. In this case, the presence of the methyl group attracts a class of proteins known as methylated-DNA binding proteins (see Deaton & Bird, 2011). These proteins, in turn, attract an entire cluster of proteins that form a repressor complex, which includes active

mediators of gene silencing. The HDACs (see preceding text) are a critical component of the repressor complex. HDACs prevent histone acetylation and favor a heterochromatin (closed) state that constrains transcription factor binding and gene expression (Figure 25.2 and see preceding text). DNA demethylation associates with a return to an open chromatin state that occurs subsequent to specific histone modifications (Weaver *et al.*, 2007).

Collectively, these modifications alter the structure and chemical properties of the DNA, and thus gene expression. As such, modifications to the DNA and its chromatin environment can be considered phenotypes which provide an additional layer of information on genomic function. Furthermore, unlike the underlying DNA sequence, which remains static across development, epigenetic modifications are dynamically regulated and responsive to changes in the environment. This is illustrated using the example of DNA methylation; however, it should be noted that other chromatin modifications also show dynamic change across development.

DNA methylation in development

DNA methylation patterns were once thought to be overlaid upon the genome only during early periods in embryonic development. Indeed, DNA methylation is considered a fundamental feature of cell differentiation. It is important to consider a simple feature of cell biology: all of the 300 or more cell types in the human body share the same DNA. Thus, the processes of cell specialization, whereby liver cells specialize in functions related to energy metabolism and brain cells establish the capacity for learning and memory, involve silencing certain regions of the genome in a manner that is specific for each cell type. Such processes define the function of the cell type. DNA methylation is considered a mechanism for the genomic silencing that underlies the cell specialization. Similarly, DNA methylation and other epigenetic mechanisms play a critical role in gene silencing during X chromosome inactivation (in females) and genomic imprinting. X inactivation is a mechanism to compensate for the greater number of genes found on the X sex chromosome relative to the Y sex chromosome. This results in the random silencing of one of the two X chromosomes in females (XX). X inactivation is implicated in childhood developmental disorders such as fragile X and Rett syndromes, which arise from the dysregulated expression of genes located on the X chromosome. Conversely genomic imprinting describes the silencing of one copy of a gene in a parent-of-origin fashion. Alleles which are “maternally imprinted” are silenced and thus “paternally expressed” and vice versa. Examples of imprinting-related disorders include Angelman and Prader–Willi syndromes arising from a cluster of imprinted genes on chromosome 15 (see Lee & Bartolomei, 2013; Keverne, 2014; and Chapter 54 for more information).

Such events, such as cell specialization and imprinting, occur early in development and are considered to be highly stable, such that de differentiation (whereby a cell loses its specialization) is rare, and often associated with organ dysfunction and pathology.

These developmental processes left the impression that under normal conditions DNA methylation occurs early in embryonic life and is irreversible. This perspective was further reinforced by findings showing that an alteration of DNA methylation at critical genomic targets (i.e., tumor suppressors) is associated with cancer (Hansen *et al.*, 2011).

At this point, dynamic changes in DNA methylation were of considerable interest for developmental biologists, but somewhat less so for mental health practitioners, who study the aftermath of more subtle variations in neuronal differentiation that occur in later periods of development or even in the fully mature brain. The studies reviewed here provide an important revision to this perspective.

There is now considerable evidence from neuroscience and other fields, including immunology and endocrinology, that the state of DNA methylation at specific genomic sites is indeed dynamic even in adult animals. Moreover, alterations in DNA methylation are emerging as the candidate mechanism for the effects of early experience in individual differences in neural function as well as in learning and memory. Thus, while the assumptions concerning DNA methylation appear valid for the examples cited, recent studies reveal that DNA methylation patterns are actively modified in mature (i.e., fully differentiated) cells, including, and perhaps especially, neurons, and that such modifications can occur in animals in response to cellular signals driven by environmental events. For example, variations in the diet of mice during gestation or later in development, such as the early post weaning period, can stably alter the methylation status of the DNA (Cooney *et al.*, 2002; Waterland & Jirtle, 2003). Likewise, both mature lymphocytes (Murayama *et al.*, 2006) and neural tissue (Martinowich *et al.*, 2003; Champagne *et al.*, 2006; Guo *et al.*, 2011; Herb *et al.*, 2012) show changes in the DNA methylation patterns at critical genomic regions in response to environmental stimuli that stably alter cellular function. The ability of environmental signals to actively remodel epigenetic marks that regulate gene expression is a rather radical change in our understanding of the environmental regulation of gene expression. Such epigenetic modifications are thus a candidate mechanism for the environmental “programming” of gene expression and, potentially, vulnerability to mental illness.

Studies of development are replete with examples of the environmental programming of gene expression. Such studies commonly report that a variation in the early environment associates with changes in gene expression and biological function that persists into adulthood and thus well beyond the duration of the relevant environmental event. In the rat, for example, prenatal nutrient deprivation or enhanced exposure to hormonal signals associated with stress stably alter, or program, the activity of genes in the liver and other sites that are associated with glucose and fat metabolism, including the gene for the glucocorticoid receptor (GR) (Gluckman & Hanson, 2007; Jirtle & Skinner, 2007; Meaney, 2007; Seckl & Holmes, 2007). These findings are assumed to represent instances in which the operation of a genomic region in adulthood varies as a function of early environmental influences. The results of recent studies suggest that

such programming effects can derive from gene–environment interactions in early life that lead to a structural alteration of the DNA, which in turn mediates the effects on gene expression as well as more complex levels of phenotype. These studies were performed in rodents, but were inspired by the vast literature reporting the pervasive effects of family environment on health outcomes in humans (Repetti *et al.*, 2002).

Maternal regulation of stress reactivity in the offspring

Naturally occurring variations of maternal care in the rat are studied with simple, albeit time-consuming observations of animals in their home cages (Champagne *et al.*, 2003). One behavior, pup licking/grooming (LG), is highly variable across mothers. Dams for which the frequency of pup LG over the first week after delivery is 1 standard deviation (SD) > than the mean for the breeding cohort are designated as high LG mothers. Those for which the frequency of pup LG lies 1 SD < the mean are considered as low LG mothers. Such variations in the frequency of pup LG are highly stable over days and even across litters.

Pup LG is a major source of tactile stimulation for the neonatal rat that regulates endocrine and cardiovascular function in the pup (Hofer, 1984; Schanberg *et al.*, 1984; Levine, 1994).

The tactile stimulation derived from pup LG increases levels of growth hormone and decreases that of adrenal glucocorticoids. Together, these effects would be expected to promote somatic growth. The question then was whether such variations in pup LG might stably alter the development of individual differences in behavior and physiology.

Our findings revealed considerable evidence for the effect of maternal care on the behavioral and endocrine responses to stress in the offspring, as well as a range of associated phenotypes (Table 25.1). The male or female adult offspring of high LG mothers show more modest behavioral and endocrine responses to stress compared to animals reared by low LG mothers. Specifically, the offspring of high LG mothers show reduced fearfulness and more modest hypothalamic-pituitary-adrenal (HPA) responses to acute stress. Cross-fostering studies, where pups born to high LG mothers are fostered at birth to low LG mothers (and vice versa), or neonatal handling studies, which significantly increase maternal LG, reveal a direct relationship between maternal care and the postnatal development of individual differences in behavioral and HPA responses to stress (Francis *et al.*, 1999; Caldji *et al.*, 2000; Caldji *et al.*, 2003; Weaver *et al.*, 2004). In the cross-fostering studies, the rearing mother determined the phenotype of the offspring. Handling-induced increases in maternal LG also reverse the phenotypes associated

Table 25.1 Maternal postnatal licking and grooming (LG), offspring phenotype and reversal of maternal effects through cross-fostering or neonatal handling.

Measure/offspring phenotype	Maternal LG	Is it possible to reverse the maternal effect through cross fostering/neonatal handling? ^a
<i>HPA-axis function/regulation</i>		
ACTH response to acute stress	High < Low	–
CORT response to acute stress	High < Low	Yes, handling reduces the CORT response to stress
<i>Hippocampal GR</i>		
mRNA expression	High > Low	Yes, handling increases GR expression in offspring from low LG dams
Protein expression	High > Low	–
GC negative feedback sensitivity	High > Low	–
PVNH CRF mRNA expression	High < Low	Yes, handling decreases CRF in offspring from low LG dams
<i>Fearfulness/Anxiety-like behavior</i>		
Fear reactivity	High < Low	–
Novelty-suppression of feeding	High < Low	–
Contextual fear conditioning	High < Low	–
Open-field exploration	High > Low	Yes, reversed by cross-fostering
<i>Learning and memory</i>		
Morris water maze learning latency	High < Low	Yes, in part: low LG offspring raised by high LG dams show reduced latency. No cross-fostering effect in high LG offspring raised by low LG dams
<i>Sexual maturation/behavior</i>		
Vaginal opening	High > Low	–
Sexual receptivity (lordosis rating)	High < Low	Yes, in part: low LG offspring raised by high LG dams show improved decreased receptivity, no cross-fostering effect in high LG offspring raised by low LG dams

ACTH = adrenocorticotrophic hormone; CRF = corticotropin releasing factor; CORT = corticosterone; GC = glucocorticoid; PVNH = hypothalamic paraventricular nucleus; HPA = hypothalamic pituitary adrenal; – = data not available.

^aNeonatal handling significantly increases maternal LG to levels comparable with high LG dams.

with decreased maternal licking (Francis *et al.*, 1999). Thus, variations within a normal range of parental care can dramatically alter phenotypic development in the rat. It is nevertheless interesting to note that some of the phenotypic differences associated with variations in pup LG are only partly reversed with postnatal cross-fostering or neonatal handling (Table 25.1). These findings suggest possible *in utero* influences that have been confirmed at least with respect to the development of individual differences in hypothalamic-pituitary-ovarian function and sexual behavior in the female offspring (Cameron *et al.*, 2008; Borrow *et al.*, 2013) and metabolic function (Kappeler *et al.*, unpublished).

The differences in the HPA response to stress in the offspring of high and low LG mothers is mediated by a maternal effect on the expression of the GR gene (*Nr3c1*) in the hippocampus (Weaver *et al.*, 2004; Weaver *et al.*, 2007). The GR is a ligand-gated nuclear receptor, which, when bound by glucocorticoids (corticosterone in most rodents and cortisol in humans), is activated and translocated to the cell nucleus where it functions as a transcription factor that regulates gene expression. GR activation in the hippocampus associates with the activation of a negative-feedback signal that regulates corticotropin-releasing factor (CRF) expression in the hypothalamus. Since CRF serves to activate the pituitary-adrenal stress response, negative-feedback regulation serves to moderate the magnitude of the stress response. The offspring of high, compared with low LG mothers, show increased hippocampal GR expression, more efficient negative-feedback regulation of CRF, reduced hypothalamic CRF expression and more modest HPA responses to stress (Table 25.1).

Persistence is a critical feature of the maternal effects described. The differences in the frequency of pup LG between high and low LG mothers are limited to the first week of postnatal life. And yet the differences in gene expression and neural function are apparent well into adulthood. We hypothesized that maternal licking might activate intracellular signals that would lead to a stable epigenetic state on the region of the genome that regulates GR expression, thus serving to sustain the “maternal effect” on GR expression.

The focus of the epigenetic studies is the nerve growth factor-induced protein A (NGFI-A) binding site in exon 1₇, a specific coding region, of the GR gene promoter. Importantly, NGFI-A is a transcription factor that activates GR expression in hippocampal neurons. Pups reared by high LG mothers show increased NGFI-A expression in hippocampal neurons as well as an increased binding of NGFI-A to the exon 1₇ promoter sequence (Weaver *et al.*, 2007; Hellstrom *et al.*, 2012). Moreover, the binding of NGFI-A to the exon 1₇ promoter sequence is actively regulated by mother–pup interactions, such that there is increased NGFI-A bound to the exon 1₇ promoter immediately following a nursing bout, but not at a period that follows 25 min without mother–pup contact (Hellstrom *et al.*, 2012). This effect is mediated in part through the increased circulating levels of thyroid hormone (T3) in pups from high LG dams, which drives hippocampal serotonin (5-HT) activity and downstream effects

Figure 25.3 Maternal licking and grooming and demethylation of the glucocorticoid receptor gene in the hippocampus of her offspring. The tactile stimulation associated with pup licking and grooming leads to increased thyroid hormone (T3) conversion in the plasma of offspring from high LG dams. This increases levels of serotonin (5-HT, blue circles) within the hippocampus. Serotonin acts via 5-HT₇ receptors to activate an intracellular signaling cascade involving cyclic AMP (cAMP, light blue oval) and protein kinase A (PKA, dark blue oval). This culminates in increased binding of a CREB binding protein (CBP, light oval with navy border) and nerve growth factor inducible-A (NGFI-A, dark blue rectangle) complex with the NGFI-A binding site (dark blue square) in the promoter of the glucocorticoid receptor gene (*Nr3c1*). Binding of NGFI-A to its consensus binding site leads to the demethylation of a nearby methylated CpG (red circle) and increased expression of the glucocorticoid receptor (GR).

on NGFI-A signaling (see Figure 25.3). Binding of NGFI-A actively redesigns the methylation pattern at this region of the genome (Weaver *et al.*, 2004; Weaver *et al.*, 2007). Thus, as adults, the offspring reared by high LG mothers show very modest levels of methylation at the CpG close to the NGFI-A consensus sequence.

The demethylation of this CpG site occurs as a function of the same 5-HT-activated signals that regulate GR gene expression in cultured hippocampal neurons (Weaver *et al.*, 2007). Thus, when hippocampal neurons of embryonic origin are placed in culture and treated with 5-HT, which mimics the extracellular signal associated with maternal LG, this CpG site is demethylated; the binding of NGFI-A to the exon 1₇ site is critical. Hippocampal neurons that are rendered incapable of increasing NGFI-A show neither the demethylation of this CpG site nor the increase in GR expression (Weaver *et al.*, 2007). Likewise, a mutation of the NGFI-A site that completely abolishes the binding of NGFI-A to the exon 1₇ promoter also prevents the demethylation of this CpG. Finally, the infection of hippocampal neurons with a virus engineered to express high levels of

NGFI-A produces demethylation of this CpG in the exon 1₇ promoter sequence and increases GR expression. These findings provide evidence for transcription-factor-binding-dependent demethylation; however, the precise mechanism whereby the methylated cytosine is removed or modified to a demethylated state is still unknown.

In summary, the maternally induced changes in specific intracellular signals in hippocampal neurons can physically remodel the epigenome. The events described to date represent a model by which the biological pathways activated by a social event may become imprinted onto the genome. This imprint is then physically apparent in the adult genome, resulting in stable alterations (or programming) of gene expression. Importantly, our findings at the molecular level co-vary with marked and persistent differences in anxiety- and depressive-like behavior in these adult offspring, underscoring the influence of maternal care in early life on phenotypes of clinical relevance. Similar findings have been reported for other models of early life stress in rodents (Mueller & Bale, 2008; Murgatroyd *et al.*, 2009) and non human primates (Provençal *et al.*, 2012), demonstrating lasting maternal effects on the epigenome and the associated neurobehavioral phenotype of her offspring. The Murgatroyd study in particular parallels findings from our laboratory as it elegantly shows an influence of maternal separation on the expression of the hypothalamic vasopressin gene, which in turn regulates HPA responses to stress.

The human early environment and DNA methylation

The persisting effects of the early environment on DNA methylation were first documented in clinical studies of maternal undernutrition in the context of the Dutch Hunger Winter (see Chapter 12). Maternal periconceptual famine exposure was associated with decreased methylation of *IGF2*, an important regulator of metabolism, in prenatally exposed individuals (Heijmans *et al.*, 2008). The results of these analyses are in line with rodent studies described earlier, which show a marked effect of maternal nutrition on epigenetic processes in her offspring. A critical question is whether familial influences operating during early development in humans are linked to the stable epigenetic regulation of gene expression in a manner comparable to that revealed in rodent studies, despite the multitude of environmental influences experienced during human development. Human studies using brain tissue collected from suicide victims have helped address this question.

Approximately a third of suicide victims have histories of childhood adversity, including childhood sexual and physical abuse, as well as parental neglect. At least two studies have shown decreased hippocampal GR expression in samples from suicide completers with histories of childhood maltreatment compared with controls (sudden, involuntary fatalities) (McGowan *et al.*, 2009; Labonte *et al.*, 2012). Forensic interviews that establish developmental history and mental health status of these suicide

victims (Dumais *et al.*, 2005; Zouk *et al.*, 2006) showed that there was no significant correlation between major depressive disorder or substance disorders with hippocampal GR expression. Rather, the decreased hippocampal GR expression was associated with a history of childhood maltreatment. There were no differences in hippocampal GR expression in samples from suicides negative for a history of childhood maltreatment. Instead, the differences in hippocampal GR expression were unique to suicide completers with a history of childhood maltreatment. These expression differences correlated with differential DNA methylation patterns between groups in the corresponding exon 1 variant promoters. The exon 1_F sequence, of particular interest as it is the homologue of the rat exon 1₇, is highly expressed in the brain and contains an NGFI-A response element (Turner & Muller, 2005; McGowan *et al.*, 2009). Moreover, the exon 1_F sequence shows increased DNA methylation and decreased NGFI-A binding in samples from suicide victims with a history of maltreatment. These findings bear considerable similarity to the maternal effect in the rat and are suggestive of early environmental regulation of the neural epigenome in humans. Recent studies in independent human samples investigating the effects of early environmental adversity on exon 1_F methylation reported consistent results (Radtke *et al.*, 2011; Tyrka *et al.*, 2012; and see later). In parallel, several studies have carried out genome-wide analyses characterising the widespread epigenetic changes observed following early adversity.

The English and Romanian Adoptee study (see Rutter *et al.*, 2012) and the Bucharest Early Intervention Project highlight the profound influence of the early care environment on child neurodevelopment and vulnerability for mental disorder (O'Connor *et al.*, 2000; Nelson *et al.*, 2007; Rutter *et al.*, 2012). Such cohorts are fertile ground for epigenetic studies. Recent findings indicate that children deprived of parental care show distinct epigenetic changes at least into adolescence (Naumova *et al.*, 2012). Naumova and colleagues (2012) assessed the methylation status of approximately 27,000 CpGs (~0.1% of CpGs in the human genome) in 14 children raised in federal institutions and 14 controls, ranging in age between 7 and 10 years of age. The authors state that a shift toward hypermethylation of a small subset of target genes associated with immune response and cellular signaling was observed in the institutionalized group. While the functional effects of these epigenetic changes on vulnerability for psychopathology remain to be clarified, this study provides proof of principle that the absence of parental care influences DNA methylation in humans. Additional genome-wide analyses of DNA methylation reveal the persisting effect of early adversity on the methylome (Labonte *et al.*, 2012; Essex *et al.*, 2013; Mehta *et al.*, 2013; Yang *et al.*, 2013). Similarly, maternal stress, especially early in infancy, is predictive of DNA methylation profiles assessed in cheek swab DNA samples at age 15 years (Essex *et al.*, 2013). More recently, Mehta and colleagues (2013) show that childhood adversity associates with coordinated epigenetic and

transcriptional changes in peripheral blood cells from adults with PTSD (Mehta *et al.*, 2013). Interestingly, despite a similar clinical presentation for both groups (i.e., PTSD), early life adversity was associated with an almost unique transcriptional profile, relative to PTSD patients without early life exposure, suggesting differential regulation of gene transcription in this group. Collectively, these studies suggest that the early social environment influences epigenetic mechanisms both in neural tissue and peripheral sources. More specifically, the work of Essex and colleagues demonstrates a distinct maternal stress effect on DNA methylation in adolescent children. This effect was most pronounced when maternal stress was experienced early in life and associated with a greater number of CpGs than paternal stress. Similarly, Provençal *et al.* (2012) show a profound influence of maternal rearing on DNA methylation across blood and brain using samples from non human primates. A question remains about the functional importance of these changes, which will need to be addressed with appropriate *in vitro* models examining individual sites. Moreover, the statistical models used to detect affected CpGs remains an issue of some debate and existing reports of the actual number of differentially methylated CpG sites should be considered as estimates. Perhaps a greater concern is the degree to which DNA methylation profiles established in peripheral sources of DNA are informative about epigenetic mechanisms within the brain.

Tissue specificity: DNA methylation in blood and brain

As discussed, DNA methylation is, in part, responsible for cell-fate specification. As such DNA methylation is tissue and indeed cell-type specific (Deaton *et al.*, 2011). This poses a challenge to researchers studying DNA methylation in the context of child mental health where access to neural tissue is not possible. A number of recent studies have addressed this issue by comparing DNA methylation profiles in both blood and brain.

Ursini and colleagues (2011) report findings from a sample of healthy young adults in which an interaction between stressful life events and catechol-o-methyltransferase (*COMT*) genotype predicts *COMT* methylation in peripheral blood and working memory performance during an fMRI task. The authors use paired adult rat prefrontal cortex and blood samples to demonstrate a moderate correlation between *COMT* methylation across tissues ($r=0.50$); however, the degree of association in human samples is unknown. This study uses a very appropriate approach. The correspondence between methylation states in brain and peripheral tissues is likely to vary as a function of genomic region. Focusing on candidate genes is a valuable complement to studies using genome-wide assessments.

Provençal *et al.* (2012) used a genome-wide approach to describe the long-term effects of the early rearing environment on DNA methylation in the blood and brain of adult rhesus macaques. Maternal versus peer rearing, a manipulation

which leads to persistent and marked changes in behavior and stress reactivity, associates with differential methylation of 1981 methylation sites in the prefrontal cortex, but only 227 sites in a selected peripheral T-cell population. A weak correlation was observed between differentially methylated sites between the two tissues ($r=0.07$). It should be noted that this study focused exclusively on gene promoter methylation. In humans, Davies *et al.* (2012) provide a comprehensive description of DNA methylation in six cortical regions, the cerebellum and matched peripheral whole blood samples. DNA methylation within each brain region clusters together and is clearly distinct from blood. Remarkably, between-individual differences in DNA methylation identified in blood were correlated with between-individual differences in brain samples ($r=0.66-0.76$). This study contrasts with the findings of Provençal *et al.*, which examined direct correlations of absolute methylation levels across tissues rather than between-individual differences across tissues. Collectively, these studies suggest that peripheral sources of DNA may be somewhat informative for identifying individual differences in DNA methylation of relevance to neural processes. However, an important caveat to the Davies *et al.* study, and to genome-wide analyses in general, is that large regions of the genome (e.g., retrotransposons) should be highly methylated regardless of cell type. The inclusion of such regions into analyses is likely to inflate the degree of correspondence across cell types. Indeed, it is highly likely that correspondence across tissues will depend upon the genomic region under study. Moreover, the effects of certain environmental conditions, such as those that activate steroid hormones or cytokines that act widely across a range of tissues, might reveal greater correspondence. In addition to questions regarding tissue specificity, an increasing number of studies assess the stability of methylation over time. This issue is critical for studies examining the potential of DNA methylation marks to serve as a peripheral biomarker for vulnerability to psychopathology.

The role of DNA methylation in developmental processes such as X-inactivation, genomic imprinting and tissue differentiation suggests that DNA methylation is a highly stable epigenetic modification. Nevertheless, at certain sites DNA methylation can be dynamic. Cross-sectional, longitudinal and twin studies now describe variation in DNA methylation across development. A study in newborns and centenarians reports more widespread hypomethylation and greater variability in DNA methylation between CpG sites in the elderly relative to the more uniformly methylated newborn DNA (Heyn *et al.*, 2012). Similarly, Fraga and colleagues (2005) show increasing epigenetic discordance in monozygotic twins across ages. Indeed, discordance in DNA methylation between monozygotic twins is evident at birth, suggestive of intrauterine and/or stochastic effects on DNA methylation early in life (Kaminsky *et al.*, 2009; Gordon *et al.*, 2012). Rates of change in DNA methylation may not be linear across the lifespan, with studies suggesting more dynamic change between 3 and 17 years, a period

encompassing puberty (Alisch *et al.*, 2012). Two longitudinal studies examine the stability of DNA methylation in infancy. Wang and colleagues (2012) examine DNA methylation in umbilical cord and venous blood samples at birth and the first 24 months of life (average follow-up was 12 months of age). The authors report remarkable stability over time with significant changes occurring at <1% of methylation sites assessed. In contrast, Martino and colleagues (2011) show more dynamic change in mononuclear cell DNA methylation in their study of 0- to 5-year-olds. In DNA methylation profiles from female newborns, 1- and 5-year-olds tended to form distinct clusters, while the 2.5-year-old group clustered with both 1- and 5-year-olds. Such individual differences in DNA methylation in the postnatal period may point to differential susceptibility of certain individuals to environmental factors such as parenting behaviors, which can influence DNA methylation. Moreover, there is likely to be variation in the stability of DNA methylation as a function of cell type, with perhaps the more phenotypically variable cells associated with immune function showing greater variation than those in other cell types.

Collectively, these studies provide important information on the dynamics of DNA methylation over time and across tissues. The methylation data from twin and multigenerational studies are particularly noteworthy as they suggest a strong genetic influence on epigenetic modifications such as DNA methylation (see later). Indeed, an exciting area of current research in epigenetics is the characterization of gene \times environment ($G \times E$) interactions at the molecular level.

The molecular definition of gene \times environment interaction

Genetic polymorphisms and epigenetic modifications both influence gene transcription. It is important to emphasize that these are coordinated and often interdependent processes. For example, a methylated cytosine is more readily mutated to thymine leading to mismatched guanine–thymine pairs, which are further modified to create an adenine–thymine (A–T) bond. This process may, in part, explain the reduced frequency of CpGs across the human genome (see Deaton & Bird, 2011). Similarly, genotype is an important determinant of the epigenetic landscape (Lienert *et al.*, 2011). An analysis of DNA methylation in six individuals from a three-generation family illustrates that DNA methylation reflects genetic relatedness (Gertz *et al.*, 2011). This study demonstrates that many of the genetic effects identified in related individuals are also seen in unrelated individuals with similar genotypes. There are widespread effects of genotype on DNA methylation in the human brain (Zhang *et al.*, 2010) with some evidence that genotype–methylation associations are conserved across peripheral and neural tissues (Docherty *et al.*, 2012; Klengel *et al.*, 2013).

Genotype may influence DNA methylation in a number of ways. Genetic polymorphisms (see Chapter 24) such as single

nucleotide polymorphisms (SNPs), variable number tandem repeats and copy number variants may introduce or remove CpGs, thereby adding (or removing) potential sites for methylation. Genetic polymorphisms that modulate transcription factor binding may also influence DNA methylation events. Increased transcription factor binding can protect CpG islands from DNA methylation and vice versa (Lienert *et al.*, 2011; Stadler *et al.*, 2011). Both gene promoter and more distal regulatory regions appear to be influenced by transcription factor binding in this way. Collectively, these findings point to a strong association between genotype and DNA methylation. Furthermore, there is emerging evidence that such genotype–methylation interdependency may be influenced by the early environment (Ursini *et al.*, 2011; Vijayendran *et al.*, 2012; Klengel *et al.*, 2013). These allele-specific effects may provide a biological mechanism to explain statistical $G \times E$ associations.

The concept of $G \times E$ effects on vulnerability for mental disorder has been a major paradigm shift in child psychiatry (Caspi & Moffitt, 2006; Meaney, 2010). Environmental factors such as childhood maltreatment (Caspi *et al.*, 2002), stressful life events (Caspi *et al.*, 2003) and cannabis use (Caspi *et al.*, 2005) interact with genetic risk factors to predict risk of later mental disorder. These reports have been supported and extended by clinical and basic research over the past 15 years (however, see Risch *et al.*, 2009; but also Rutter *et al.*, 2009; Meaney, 2010). More recently, $G \times E$ effects have been reported, which provide preliminary support for the parental signaling hypothesis and vulnerability for mental disorder. For example, children carrying the dopamine receptor D4 (DRD4) 7-repeat polymorphism show both the *highest* and *lowest* risk of adverse neurodevelopmental outcomes as a function of maternal sensitivity or an enriched early care environment (Berry *et al.*, 2013; Belsky & Pluess, 2013). Replication of these findings is required, but such studies are beginning to provide some clues as to why some children may be more, or less, sensitive to the quality of the early care environment.

Despite an increased appreciation for the importance and biological plausibility of $G \times E$ effects, the molecular basis for these associations remains poorly defined. Epigenetic modifications, such as DNA methylation, provide a mechanism to link genetic and environmental risk to phenotype (Meaney, 2010; Klengel *et al.*, 2013). In addition to our work in rats, two recent human studies provide evidence for a molecular definition of $G \times E$ effects. The first, drawn from the Iowa adoption study, demonstrates that exposure to childhood sexual abuse and carriers of the short version of the serotonin transporter (*SLC6A4*) repeat polymorphism interact to predict decreased methylation of a CpG within *SLC6A4*. More recently, Klengel and colleagues (2013) provide a comprehensive description of allele-specific demethylation of the GR co-regulator FK506 Binding Protein 5 (FKBP5) in adults exposed to childhood trauma. This study demonstrated that polymorphisms in *FKBP5* influence the position of the nucleosome, which, when combined with childhood trauma (postulated to increase circulating cortisol),

results in an increased risk of PTSD. At the molecular level, this interaction is associated with stable DNA demethylation, which in turn predicted symptoms of glucocorticoid resistance and hippocampal volume. In line with what is known about the capacity for transcription factors to modulate local DNA methylation levels, a large emphasis is placed on the presence of a glucocorticoid-binding site within the DNA, which may be an important factor for such demethylation events. Ursini and colleagues (2011) also provide evidence that environmental stress associates with allele-specific changes in *COMT* methylation, which associate with cognitive performance. In summary, these studies build on epidemiological analyses of G×E effects by providing a functional mechanism to link genetic risk factors and adverse environmental exposures to sustained physiological changes of relevance to mental health. Undoubtedly, both candidate gene and genome-wide analyses will uncover additional genomic regions which show epigenetic sensitivity to early adversity and the early care environment.

Methodological considerations in studies of epigenetics

The recent wave of epigenome-wide association studies reflects the growing interest in epigenetics in the field of child mental health. These analyses are beginning to uncover disease risk markers (in peripheral tissue) in conditions often associated with exposure to various adverse experiences early in life; examples include major depression (Sabunciyan *et al.*, 2012; Byrne *et al.*, 2013), PTSD (Smith *et al.*, 2011; Mehta *et al.*, 2013), schizophrenia and bipolar disorder (Dempster *et al.*, 2011). However, the application of conventional genome-wide association study (GWAS) designs may prove problematic for the field of epigenetic epidemiology. Chromatin modifications, such as DNA methylation, are dynamic and respond not only to environmental influences but also to disease processes. Therefore, it remains a challenge to identify epigenetic modifications that are causal, and not a consequence of disease processes (Mill & Heijmans, 2013). In addition, unlike conventional GWASs in which the predictor (presence or absence of genetic risk factor) is invariant over time and tissue, epigenetic phenotypes are considerably more variable. Prospective birth cohorts in which biological samples are collected longitudinally, across developmental periods and risk exposures, twin studies and *in vitro* functional analyses will all help to identify specific epigenetic phenotypes that are causally related to the risk of mental disorder (see Chapter 12).

Additional considerations for epigenome-wide analyses are the issues of statistical power and stringency. Many of the studies described employed microarray-based platforms for analysis of genome-wide DNA methylation. Currently, the Illumina human methylation 450 Beadchip (450 k) array provides the most comprehensive genome-wide coverage (~485,000 sites) at a cost that permits its use in larger scale, epidemiological-like

studies. It should be noted that despite improved genome-wide coverage, this array provides quantitative data on less than 2% of the 28 million CpGs contained in the human genome. The ever-decreasing cost of sequencing technologies will undoubtedly increase the use of next-generation sequencing for whole genome methylation analyses. While such approaches may reveal novel genomic regions of relevance to child vulnerability for mental disorder, increasing genome-wide coverage poses analytical challenges. For example, in the field of mental health, few studies to date have identified between-group differences in DNA methylation that exceed 10%. These relatively small changes in DNA methylation, combined with the large number of comparisons (~485,000 for the Illumina 450 k array) require adequately powered sample sizes to detect subtle differences in DNA methylation (Michels *et al.*, 2013). In the absence of large sample sizes, replication in independent samples is important to increase confidence in novel findings. Somewhat similar to early candidate gene association studies, the emerging field of epigenetic epidemiology is likely to identify several false positives if studies are not adequately powered and controlled.

Finally, as noted, epigenetic modifications do not occur in isolation nor are they independent of the underlying DNA sequence. Genome-wide surveys of multiple epigenetic modifications, including different forms of DNA methylation, genotype and gene expression may prove useful in clinical studies of early adversity, and will help identify novel functional loci of relevance to child mental health.

Summary and concluding remarks

We have described how maternal effects operating early in life drive phenotypic diversity across species and summarized studies in the rat that systematically examined the influence of maternal care. The offspring of mothers differing in the frequency of LG have distinct developmental trajectories and behavioral profiles, mediated in part by epigenetic regulation of gene expression. Somewhat similar data has emerged from clinical studies of early adversity, highlighting epigenetic modifications such as DNA methylation as a potential mediator of maternal effects on vulnerability for mental disorder. A challenge as we move forward with a wider application of the environmental epigenetic hypothesis to the field of child mental health is to determine to what extent epigenetic modifications can be used to identify at-risk children and treatment responses. It is also unknown if the effects of early adversity on epigenetic processes can be reversed by therapeutic interventions or if such an outcome would be desirable, given the potential adaptive value of certain modifications. Thus, while epigenetics is an exciting and rapidly growing field, translating basic scientific findings to improve clinical care and child outcomes will require continued and cautious research efforts.

Introduction

Human development is the process of individual adaptation to a complex and ever-changing environment. At times the adaptation is smooth; the environment provides support to the individual and the individual is able to use his/her own skills in a successful adaptation to the circumstance. At other times, however, the adaptation of the individual fails. This may be because the challenges in the environment are too great or the individual's abilities in adapting to the environment are insufficient. It may also be that failure to adapt is explained by the combination of individual characteristics and a challenging environment (Rutter, 2012). Most of our knowledge about psychosocial adversities and their effect on children's mental health comes from correlational studies and specific designs are needed to help us identify the mechanisms that explain why adversity and mental health are correlated. These designs are discussed in Chapter 12.

Conceptual issues in the effects of psychosocial adversity on children

Transactional processes between individuals and their environments

Although we know that risky environments increase mental health problems in children, characteristics of children can also influence exposure to environmental adversities. Several types of mechanism operate. First, characteristics of children elicit environmental experiences. Children who are hyperactive, impulsive, and negative in their mood elicit more negativity from parents (Shaw *et al.*, 2001); certain children within families provoke marital conflict more than others (Jenkins *et al.*, 2005); infants who have less capacity for synchrony alter their mothers' attachment-related caregiving (Beebe *et al.*, 2010).

Second, individuals choose relationships/friends that have a negative effect on them subsequently: for example, individuals with behavioral problems befriend like individuals, who in turn increase the child's behavioral problems (Dishion & Owen, 2002). Thus, bidirectional influences are evident between people and their environment. Bidirectional effects are most often measured using cross-lagged designs (Steele *et al.*, 2013). In these designs, two processes that co-vary (e.g., parental harshness and difficult child behavior) are examined over time and the goal is to examine which of the two processes predicts change in the other more strongly. There is evidence for effects from children to parents and parents to children (Burt *et al.*, 2006).

Moderation processes in the effects of environmental adversity

Probably the most important principle in understanding the impact of psychosocial adversity is that children vary markedly in their susceptibility to environmental influences. Some are much more vulnerable to the adverse effects of psychosocial adversity. This means that although, on average, there is a raised risk to all children through exposure to risky environments, the effects come about because a subsample of children show marked responses to adversity, while others remain relatively unaffected. Individual vulnerability has been found to be explained by individual characteristics of children (El-Sheikh, 2005), but also by the presence of good relationships in children's lives (Gass *et al.*, 2007), issues discussed in Chapter 27.

Mediation: from distal to proximal risks

Bronfenbrenner (1977) proposed a model for understanding context effects on children. He suggested that development occurred within embedded "layers" of context to children, from macro systems (country and community influences) to micro systems (children's experiences in families, schools, peer groups, and childcare centers). Ecological models stress these

layered influences (Ungar *et al.*, 2013). Within these models, both “macro” and “distal” refer to more distant stressors and “micro” and “proximal” to stressors that are closer to the child. These terms are generally utilized within mediation models. A mediation model requires a significant pathway from the distal process to the child outcome, through the proximal process; for example, cumulative environmental risk leads to greater differential parenting, which in turn explains child behavior (Meunier *et al.*, 2013). Mediation models are considered to be “causal” models: the mediator is conceptualized as the active agent that is causally responsible for the relationship between two other variables. It is important to note, however, that theories of causation are very discipline based and influenced by our current scientific knowledge. For example, although “parenting” offers a causal mechanism for behavioral scientists, for neuroscientists mediation is about brain mechanism (Hanson *et al.*, 2013) and for cognitive psychologists it is about cognitions (White *et al.*, 2011). Further, our mediation models only represent short sequences of process when in reality long chains of sequenced influences, across many cognitive and neural systems, are likely to be operating.

Developmental timing

The effect of psychosocial adversity on mental health could vary depending on the developmental period during which it occurs. Such an impact, via the embedding of stress in biological and cognitive systems (see Chapter 23), could be greater in childhood when the brain is developing rapidly and cognition is still consolidating. Alternatively, adolescence, which brings pubertal changes, could also be a time of increased sensitivity to the effect of adversity. Questions relating to the timing of psychosocial adversity and stress on the development of mental health difficulties are hardly testable with human samples. Individual changes are examined in longitudinal observational studies but causality can only be implied by this study design, and not tested properly. Natural experiments, embedded in a longitudinal design, offer the strongest research opportunities to test questions of developmental timing. A useful example is the English and Romanian Adoptee Study, which follows the developmental milestones of children who were placed in institutional care at an early age (see Rutter *et al.*, 2012). The timing of institutional deprivation and its impact on children’s development was extensively documented through the years. Findings indicate that when institutional deprivation ceased within children’s first 12 months of life, poor outcomes are not as severe as when deprivation persists beyond the first year of life. Similar conclusions were reached by another study of adoptees, the Bucharest Early Intervention Project (Nelson *et al.*, 2007).

Studies examining the effect of developmental timing should consider the possibility that psychosocial adversity in infancy/early childhood may represent a longer duration or persistence of stress, and should control for this confounding effect. Controls should also be considered for factors that may predispose some children to experience psychosocial adversity

in the first place. Animal research allows a stricter control over the concept of adversity and stronger conclusions with regard to developmental timing. However, findings so far are still inconclusive (Tottenham & Sheridan, 2009).

Empirical findings on distal risk factors

Neighborhood influences

Deprived neighborhoods are characterized by high unemployment rates, predominantly minority populations, dense public housing, crime and violence, as well as social isolation. Research on the influence of neighborhoods on children’s mental health has the challenge of differentiating between the impact of families’ socioeconomic status (SES) and the neighborhood in which they live, given that SES constrains families’ choice of neighborhood. One review estimated that effects of deprived neighborhoods accounted for between 5% and 10% of variance observed in children’s developmental outcomes (Leventhal & Brooks-Gunn, 2000); however, because of the design of these studies, it remains possible that uncontrolled effects at the individual and family levels are misattributed to neighborhoods.

Results from an experimental study, the Move to Opportunity (MTO) program, provide more compelling causal data. Families recruited from high-poverty neighborhoods in the United States were randomly assigned to the experimental or control condition. Members of the experimental group were given vouchers to move to a low-poverty area. Approximately 40% of families in the experimental condition took up the option of moving and effects were calculated for all families. Although initially beneficial effects on school achievement were notable for both girls and boys, later follow-ups suggested that only girls benefited from the intervention (Ludwig *et al.*, 2012) and lasting effects were only seen for specific outcomes in girls (psychological distress and obesity).

One component of the neighborhood effect is likely to be exposure to violence. Gorman-Smith and Tolan (1998) interviewed African-American and Latino adolescents in public high schools in deprived neighborhoods in the Chicago area, with the majority of the sample living in poverty. They found that 16.5% reported that a family member had been robbed or attacked and 15.6% had seen someone shot or killed in the previous year. A meta-analysis of community violence and children’s mental health showed that violence in neighborhoods was moderately to strongly associated with children’s symptoms with the strongest effects seen for PTSD ($d = 0.79$) and behavior problems ($d = 0.63$). It should be noted, though, that these effect sizes are not independent of family SES (Fowler *et al.*, 2009).

Exposure to war

Children in war zones can be exposed to a wide range of traumatic events including famine and thirst, loss of family members and homes, seeing dead and injured people, rape, physical injury, threats to life and being taken prisoner (Drury & Williams, 2012). In a population of children who experienced

the Rwandan genocide, 78% experienced a death in the family, while 70% saw someone being killed or injured, and 15% reported hiding under a dead body to escape detection during the massacre (Dyregrov *et al.*, 2000). A meta-analysis of mental disorders among children exposed to war showed that rates of PTSD were 47%, with rates of depression and anxiety also elevated (Attanayake *et al.*, 2009).

Socioeconomic status

Societies are hierarchically organized along an economic dimension. Both absolute levels of income and the extent of the difference between rich and poor members of the society have been found to be a consistent correlate of mental and physical health. With respect to absolute deprivation, Slopen *et al.* (2010) showed that children who had experienced persistent food insecurity were twice as likely to suffer from externalizing problems compared to children without such insecurity. Macmillan *et al.* (2004) found that the number of years of living in poverty was strongly associated with initial levels of antisocial behavior. Further, children exposed to persistent poverty, those who only moved out of poverty for a short time, and those who moved into poverty, showed faster *rates of change* on antisocial behavior than children who had never lived in poverty. Two direct effects to account for this relationship have been hypothesized: inequitable allocation of resources like nutrition, healthcare, housing, and education and the development of negative health behaviors such as low exercise and tobacco use (Bradley & Corwyn, 2002). SES effects on children's developing brains have been noted to be strongest for brain areas related to language, executive function, and attention (Hackman & Farah, 2009). Stevens *et al.* (2009) assessed children between 3 and 8 years using event-related potential and found that children in low SES homes, compared to their middle SES counterparts, showed a brain pattern indicative of trouble suppressing distracting information.

Relative income also plays a role in health outcomes. Wilkinson and Pickett (2009) developed an inequality metric by examining the ratio of incomes for the top and bottom 20% of a society across countries. This metric explained variation across countries in many health and learning outcomes for children. Absolute levels of income have been found to explain more variance in health outcomes than relative income (Kondo *et al.*, 2009; Olson *et al.*, 2010). A clever brain-imaging experiment (Dohman *et al.*, 2011) shows that a region of the brain that registers reward (the ventral striatum) becomes activated by relative income. This activation was evident the more discrepant the advantaged persons were from their partner with respect to financial rewards given for task performance. This finding provides evidence for one neurobiological system that may be implicated in the effects of relative income on health outcomes.

Effects of poverty on children mediated by parenting

Parenting has been found to play a mediating role in the relationship between socioeconomic adversity and children's

well-being (Grant *et al.*, 2003). Low SES makes it more likely that parents show high levels of hostile inconsistent parenting, less sensitivity, and parental investment, and expose children to lower levels of cognitive stimulation. Several studies have tested mediation models in which the indirect effect of SES on children's mental health through exposure to adverse parenting has been supported (Grant *et al.*, 2003; Gershoff *et al.*, 2007).

Cumulative risk

Risk factors for children's development rarely operate in isolation. For example, living in poverty is associated with single parenthood, parental psychiatric disorders, and greater marital conflict. This means that by looking at the impact of single risks we fail to capture the degree of risk exposure that children experience. Cumulative risk indices are simply a count of the number of risks to which children are exposed and this has been found to explain more variance in child outcomes than single risks and both linear and nonlinear effects of cumulative risk are seen (Evans *et al.*, 2013). Nonlinear effects show that risks combine multiplicatively to influence child disorders. Effects of cumulative risk persist into adulthood and influence physical as well as mental health. For instance, adults who experienced four or more adverse childhood experiences were 3.9 times more likely to suffer from emphysema and chronic bronchitis and 2.2 times more likely to have ischemic heart disease than individuals with no adverse childhood experiences (Felitti *et al.*, 1998).

Cumulative social disadvantage and parenting

At higher levels of cumulative risk, the ability of parents to be attentive and sensitive to their children is compromised (Burchinal *et al.*, 2008). They also show more differential parenting across the sibship (Meunier *et al.*, 2013). Other mediators of cumulative risk include allostatic load (i.e., the physiological consequences of adapting to repeated stress) (Evans, 2003), sequences of risks in all periods of childhood (Appleyard *et al.*, 2005), and brain function. For instance, Hanson *et al.* (2013) show that prefrontal volume of adolescents is a mediator between cumulative life stress and spatial working memory.

Distal risks in low- and middle-income countries

The development of children growing up in developing countries and areas where conflicts prevail is precarious. Risk factors are numerous and resources scarce. The development of over 200 million children under the age of 5 years is compromised by factors such as poverty and stunting, which are common in countries in South Asia and sub-Saharan Africa (Grantham-McGregor *et al.*, 2007). These factors are associated with lower levels of achievement and poor cognitive outcomes, which in turn result in the perpetuation of poverty given the ill-preparedness of these children for the workforce in adulthood. Other factors that contribute to poor cognitive and mental health outcomes include inadequate cognitive stimulation, iodine and iron deficiencies, malaria, intrauterine growth

restriction, maternal depression, and exposure to violence (Walker *et al.*, 2007).

Empirical findings on proximal risk factors: development in the context of close relationships

Parental responsiveness

Parenting in early infancy centers on attachment processes. Bowlby (1971) proposed that the attachment system is a bio-behavioral system developed for the protection of the young. Human infants elicit caregiving through signals such as crying, and clinging, which are designed to maintain close proximity to a parent and, subsequently, safety and protection (Goldberg *et al.*, 1999). This biobehavioral system motivates the child to use the parent as a secure base from which to explore the world, and as a haven of safety in times of perceived threat or distress. The core parental mechanism of this theory is parental sensitive responding to child distress, that is, their ability to perceive and respond promptly, accurately, and sensitively to child signals and cues. Sensitive responding is associated with secure attachment relationships (van IJzendoorn, 1995). It is enduring and convincingly impacts child development across multiple domains of functioning (e.g., Fraley *et al.*, 2013). Recent theories of sensitivity suggest that synchronous responses between parents and children build the hardwiring that is essential for the social brain (Feldman, 2007).

More recently, researchers have called for a more multi-dimensional approach to parental responsiveness to enhance our understanding of the transactional nature of the parent–child relationship, and child outcomes (Kobak & Madsen, 2008). One aspect of responsiveness is maternal autonomy support, defined as the degree to which parents promote, encourage, and monitor the child's independent problem-solving and decision-making skills. The effective use of parental autonomy support predicts secure parent–child attachment and executive function (Whipple *et al.*, 2010) as well as academic success and peer relations (Joussemet *et al.*, 2005).

Recent research has focused on the parents' accurate understanding and interpretation of the child's behavior and the cognitive capacity to see things from the child's point of view, globally labeled as mind-mindedness (Meins *et al.*, 2001) and partially operationalized as mental state talk. Mental state talk is related to ratings of maternal sensitivity (Laranjo *et al.*, 2008), secure attachment (Meins *et al.*, 2001), children's later mentalistic vocabulary (Jenkins *et al.*, 2003), and harmonious peer interactions (McElwain *et al.*, 2011) (see also Chapter 37).

Parenting dimensions

The parenting dimensions described here have emerged as correlates of psychopathology in children. Associations tend to be nonspecific, with many types of parenting found to be associated with both emotional and behavioral psychopathology (Wang & Kenny, 2014; Wood *et al.*, 2003).

Harshness

The domain of parenting most consistently linked to psychopathology is parental harshness, with the most consistent links to children's externalizing behavior (Hoeve *et al.*, 2009). Harsh parenting can be viewed dimensionally with physical abuse at the extreme end of the continuum. Overt physical abuse is associated with an increased risk of both emotional and behavioral psychopathology in children (Kim & Cicchetti, 2010), as well as a myriad of physical and mental health problems in adulthood (Norman *et al.*, 2012). Effects, however, are evident all along the continuum and long before physical abuse is at issue. Harsh parenting involves verbal aggression, hostility, and criticism toward children. Even from an early age, children who are recipients of harsh and controlling interchanges with parents are more likely to show noncompliance, aggressive behavior with peers, and other behavioral problems (Smith *et al.*, 2004). Harsh parenting has been shown to predict *change* in child behavior using a longitudinal design that controls for previous behavior, lending support to the idea that harsh parenting plays a causal role in childhood disorders (Burt *et al.*, 2006) (see also Chapter 65).

Warmth

A complementary body of developmental research exists to demonstrate the importance of dyadic parent–child exchanges that are high in parental warmth. Parental warmth includes positive affect, affection, and admiration toward the child (Davidov & Grusec, 2006). Exposure to warm and responsive parenting has shown to buffer children from adverse outcomes, and, conversely, an absence of warmth has been linked to poor emotion regulation, and emotional and behavioral maladjustment (Keller *et al.*, 2008). Parental warmth moderates the association between harsh parenting and child behavioral problems, with the association being modest in high-warmth mothers and robust in low-warmth mothers (Deater-Deckard *et al.*, 2006).

Monitoring

Another dimension of parenting that is associated with psychopathology, particularly conduct problems and substance use, and particularly in adolescence, is lack of parental monitoring. Common indicators of parental monitoring include parental knowledge about where children are, who they are with and what they are doing, parental control of the child's activities and associations, and finally, the child's voluntary disclosure of information. Meta-analytic evidence suggests that all indicators of parental monitoring have a relatively similar impact on outcomes (Hoeve *et al.*, 2009). Research into parenting factors that predict a child's willingness to self-disclose suggest that a warm and responsive family climate is likely to influence the child's proclivity to disclose information (Soenens *et al.*, 2006) and this proclivity was found by Kerr and Stattin (2000) to be the best predictor of adolescent normbreaking behavior. Thus, both the child and the parent play an active role in protecting the child from maladaptive outcomes. Intervention efforts to

enhance parental monitoring practices have been effective in reducing antisocial behavior and early adolescent substance use (Dishion *et al.*, 2003).

Parenting for cognitive development

A critical developmental milestone in early childhood is the acquisition of language. Individual differences in language skills show remarkable predictive power, with early oral language predicting later academic achievement and reading comprehension (Storch & Whitehurst, 2002; NICHD Early Child Care Research Network, 2005). Parental behaviors, including sensitivity, cognitive stimulation, and parental warmth, have been consistently implicated in child language development and its sequelae. Theoretically, it is postulated that the availability of warm and responsive parent–child exchanges provide opportunities for scaffolding the child’s emergent language via focused and attuned parental behaviors that are attuned to the child’s interests and needs. Rich and interactive learning environments also promote stimulating and rewarding reciprocal verbal and nonverbal exchanges between dyads (Pungello *et al.*, 2009). Accordingly, positive parenting has been shown to mediate associations between maternal and child language skills (Taylor *et al.*, 2009). The predictive role of parenting appears enduring as positive parenting in toddlerhood predicts academic skills through to fifth grade (Cook *et al.*, 2011). Intervention research has demonstrated that enhancing parental contingent responsiveness can significantly impact the child’s language and cognitive development, supporting a causal role for responsiveness on child outcomes (Landry *et al.*, 2008).

Differential parenting

Parents have been found to be differentially positive and negative with siblings in the family. To some extent such differential treatment of children is explained by child characteristics, including age and temperament. Differential parenting predicts increased levels of disturbance in the child who receives less positivity or more negativity over time even after controlling for genetic influences (Caspi *et al.*, 2004). For a long time, differential parenting was thought of as something that was problematic for the health of the “disadvantaged” child. Recent research suggests that the dynamic is negative for the whole family. Thus, Meunier *et al.* (2013) showed that the within-family standard deviation on parenting is associated with the family average for children’s behavior problems. This suggests that it may create a dynamic in the family of divisiveness, which is problematic for everyone involved. It is interesting to note that higher levels of differential parenting predict more negative sibling relationships and the negativity of these relationships can last a lifetime (Suitor *et al.*, 2008).

The childhoods of parents

An intergenerational transmission of parenting exists: parents who experienced poor parenting in their own childhoods are more likely to engage in poor parenting with their own children,

and individuals experiencing positivity and warmth in their childhoods grow up to be more responsive parents (Belsky *et al.*, 2005; Kovan *et al.*, 2009). The same intergenerational effects have been shown for hostile parenting behavior (Neppel *et al.*, 2009). Interestingly, these intergenerational continuities are also affected by an individual’s partner choice. Conger and colleagues (Conger *et al.*, 2012) initially assessed the parenting that children received when they were young and then followed them up after they had their own children. Children who had been parented harshly were more likely, once they became adults, to choose partners who were harsh. Adults who had experienced harsh parenting in their childhoods were also more likely to parent harshly if their partner parented harshly. The impact of mental and physical illness in a parent on the children is described in Chapter 28.

Loss of a parent

The bereavement process involves demonstrations of sadness and distress that sometimes develop into more severe psychopathology. A proportion of children suffering from grief will demonstrate clinically relevant symptoms that require the attention of health professionals. For example, children who lost their parents had a higher rate of major depressive episode 2 months after their loss (24%) compared to children who did not experience such a loss (1%) (Gray *et al.*, 2011). Worryingly, 35% of bereaved children reported suicidal ideation compared to 10% of their nongrieving counterparts. Further, bereaved children had more depressive symptoms 2 years after the death of their parents than controls, but significantly less than clinically depressed children in the community (Cerel *et al.*, 2006). High family socioeconomic status and few depressive symptoms reported by the surviving parent were associated with better outcomes.

Siblings

Siblings have been shown to influence one another’s mental health both positively and negatively. On the positive side, when children are in stressful circumstances but have a sibling with whom they are close, they are less likely to show emotional and behavioral problems as a result of life events (Gass *et al.*, 2007). On the negative side, there is some evidence that older aggressive or delinquent siblings may train younger siblings in these behaviors, particularly when the relationship is a close one (Slomkowski *et al.*, 2001). These designs, however, did not take into account clustering on aggressive and delinquent behavior, which may have come about through genetic similarity of siblings. When such clustering is taken into account, this “training” effect of a sibling is not evident (Steele *et al.* 2013).

The family environment

The earlier discussion is centered on dyadic family relationships. The “whole” family environment may also be important to children’s well-being: the processes and atmosphere that operate beyond individuals and dyads. There are very few research

designs that can effectively capture the influence of the whole family, because in order to do this we must first isolate the influence of individuals and specific dyads in the family. The family-based social relations model achieves this. Every family member interacts with all other family members. Through this the following components of family life can be isolated: (a) the consistency of behavior that an individual directs to, and elicits from, others; (b) interactional behavior that is specific to each dyad in the family; and (c) the similarity of dyads within the family to one another. By taking account of the components “further down” the family system (i.e., individuals and dyads), we can achieve a real estimate of the whole family system. These studies show us that there are whole family influences. About 16% of observed negativity occurs at the family level (Rasbash *et al.*, 2011). Furthermore, when we examine change over time in sibling relationship quality based on child report and across multiple sibling dyads in the family, we find 32% of the variance for positive sibling relationships and 37% of the variance for negative sibling relationships is attributable to the family environment (Jenkins *et al.*, 2012). This shows us that we must go beyond dyadic interactions when we consider the ways in which families influence child well-being.

Peers

A similar risk mechanism to that described for siblings is likely to operate for peers. Several studies, including one involving an experimental design, have shown that peers may train one another to increased levels of deviant behavior. The most convincing demonstration of the negative impact of deviant peers comes from a group treatment study (Dishion *et al.*, 1999). The experimental group was offered treatment for their delinquency in a group setting. The treatment for the comparison group was individually administered. Boys were randomly assigned to treatments and the two groups were indistinguishable at the start of treatment. The investigators were surprised to find on follow-up that adolescents who were treated in group settings showed a major rise in delinquency over time. Through group treatment the investigators had inadvertently facilitated introductions to other delinquent youth. The boys formed groups outside of the sessions. They reinforced one another, exchanged techniques, and encouraged further delinquent activities.

Exposure to deviant peers is not only a problem in adolescence. Howes (2000) assessed levels of aggression in preschool classes in childcare settings. When the proportion of aggressive children was higher in the preschool daycare, this resulted in children being more aggressive themselves when they entered Grade 2, after taking account of children's own aggression in preschool.

A common form of peer abuse is bullying, which involves repeated hurtful actions between peers where an imbalance of power exists. Accumulating evidence demonstrates that bullying is harmful to children's well-being and increases the risk of psychopathology: victims are more at risk for anxiety, depression, self-harm, violent behavior, and psychotic symptoms than

nonvictims and these problems can last until late adolescence (Arseneault *et al.*, 2010). The effects of victimization on mental health have been shown to be over and above other hardships and genetic confounds (Arseneault *et al.*, 2008).

Being the victim of bullying is not a random event (Ball *et al.*, 2008) and is related to child characteristics such as emotional and behavioral problems (Barker *et al.*, 2008; Bowes *et al.*, 2009). The family environment also plays a role in placing some children at risk of being the victims of bullying via factors like physical maltreatment (Bowes *et al.*, 2009), parental depression (Beran & Violato, 2004), and low socioeconomic status (Wolke *et al.*, 2001). Genetic and environmental factors such as physical maltreatment contribute to the continuity of bullying victimization over time (Bowes *et al.*, 2013). Children who are victims of abuse often enter a cycle of victimization that perpetuates itself over time and across situations. Being a victim of violence places the child at increased risk of various forms of further violence (revictimization), including emotional abuse, physical abuse, sexual abuse, and Internet harassment (polyvictimization). Child victims of physical assaults were twice as likely to experience another assault a year later, and victims of sexual abuse were seven times more likely to experience the same form of abuse in that same period of time (Finkelhor *et al.*, 2007a). Further, in a national survey in the United States, out of the 71% of children who reported experiencing violence in a year, one-third reported more than one type of victimization including bullying, assaults, sexual abuse, and maltreatment (Finkelhor *et al.*, 2007b). Furthermore, children who experienced polyvictimization suffer from increased symptoms of mental health problems, irrespective of more recent victimization experiences. Factors such as having older siblings and friends were associated with desistence of victimization from one year to another while moving to a bad neighborhood was associated with persistence. Altogether, this body of evidence suggests that efforts aimed at reducing bullying victimization in childhood and adolescence should be strongly supported.

Bully-victims are children who are involved in bullying both as bullies and as victims (about 6% of bullies, Nansel *et al.*, 2004). Bully-victims have the highest level of adjustment problems among all children involved in bullying (Nansel *et al.*, 2001).

Marital conflict

Marital conflict has been found to be associated with a wide range of emotional and behavioral problems in children, with the association between the latter and marital conflict being particularly robust. A number of studies provide convincing longitudinal evidence that marital conflict influences child behavior (Davies *et al.*, 2002; Jenkins *et al.*, 2005).

The aspect of marital conflict found to be most harmful for children is openly expressed hostility or aggression. Silence, ignoring, or other unexpressed modes of unhappiness in marriage do not have the same negative impact on children, at least in the short term (Jenkins & Smith, 1991). Children rate themselves as feeling more upset by conflict that remains unresolved

between parents than conflict that is resolved (Cummings & Davies, 1994). Conflict that is about children has been found to be more distressing than conflict that is about non-child-related issues (Grych & Fincham, 1993). There is enormous variability in the extent to which children are negatively affected by marital conflict. Children's attributional processes concerning the conflict explain some of this variability. Those who perceive the conflict as threatening to family well-being (Davies *et al.*, 2002) or who blame themselves for it are more adversely affected (Grych *et al.*, 2003). The quality of the parent-child relationship has been found to be a partial mediator of the relationship between marital conflict and children's well-being (Buehler & Gerard, 2002). It should also be noted that difficult children increase the conflict between parents (Jenkins *et al.*, 2005), showing that although parental conflict has an influence on children, difficult children generate more parental conflict.

Separation and divorce

The rate of divorce has been steadily climbing. Thus, the proportion of children living apart from a biological parent is on the rise. Compared to children of intact families, children of divorced parents experience a range of negative outcomes, including behavioral problems, academic failures, as well as problems with peer relations and self-concept (Amato, 2001), which continue into adulthood (Amato, 2001). Divorce is not a discrete event: the marital conflict that usually precedes it is more problematic for children than the separation event itself (Morrison & Coiro, 1999). Consequences of divorce include economic hardship, decline in effective parental control, and diminution of noncustodial parent-child contact (Amato, 2010).

Several factors have been examined as potential moderators of divorce on child adjustment. Marital quality prior to divorce can influence how divorce is experienced: children react more adversely when there has been low parental conflict prior to divorce. When conflict is high, little change or mild improvements in child adjustment are noted when the marriage dissolves, suggesting that divorce may be more welcome in high-conflict situations (Strohschein, 2005). An emerging body of research underscores the importance of father involvement following separation and suggests that fathers' higher level of involvement promotes favorable outcomes for children but only when the father is not antisocial (Coley & Medeiros, 2007). Race has also been identified as a moderator, with European-American children experiencing a more detrimental impact of divorce compared to African-American children (Amato & Keith, 1991). It has been proposed that the nominal change in household income, as well as the more accepted norm of single parent status in the African-American community may attenuate the impact of divorce and separation for this racial group (Lansford, 2009).

Childcare influences

Childcare is a core element of most industrial societies as the majority of children attend childcare prior to school entry.

Quality and number of hours in care appear to be particularly important predictors of outcomes. Some studies have reported that longer hours predict more behavioral problems in children, although effect sizes tend to be small (NICHD, 2004). The effect of longer hours was still present on impulsivity and risk taking at age 15 (Vandell *et al.*, 2010). A meta-analysis of 20 independent samples revealed that across all ages, children in higher quality childcare had better academic, language, and social skills outcomes (Burchinal *et al.*, 2011). Peisner-Feinberg *et al.* (2001) demonstrated that, after adjusting for child and family characteristics, children's cognitive, language, and social skill gains were evident into early elementary school in children who attended high-quality childcare centers and the NICHD follow-up to 15 years has shown the same. Positive effects of childcare have been found to be strongest among socially disadvantaged children (Coté *et al.*, 2008). Both the gains associated with high-quality childcare, as well as the adverse consequences of long hours in care are enduring, but it is important to note that parenting quality appears to be a far stronger and more consistent predictor of child developmental outcomes than childcare experience (Belsky *et al.*, 2007).

Chronic versus acute psychosocial adversity

Many of the adversities described are chronic in nature. High levels of stability have been seen in risks such as marital conflict (Birditt *et al.*, 2010) and the parent-child relationship (Burt *et al.*, 2006). Within chronic exposures there are acute elements (parents are highly conflicted and then separate) which make it hard to separate the effect of chronic and acute stressors. The study of the effect of natural disasters on child well-being provides, on the surface, a more precise test of the acute hypothesis. Here too, however, chronic and acute effects are obfuscated because acute disasters often precipitate long-term problems in living. In general, findings related to natural disasters mirror conclusions from the chronic adversity studies. First, there is a dosage effect: the closer and more intense the exposure, the more negative the outcome (Masten & Osofsky, 2010). Second, when the acute event is associated with an increase in chronic adversities in the home such as family tensions and violence, then the effects on children are worse (Fernando *et al.*, 2010). Third, there is marked heterogeneity in reactions to disaster with predisaster symptomatology explaining some of this heterogeneity (Pine *et al.*, 2005).

Summary of findings related to psychosocial adversity causing child psychopathology

The evidence suggests that exposure to a range of environmental adversities increases the risk of disorder in children through the biological embedding of environmental risk. Environmental influences are best conceptualized as embedded layers of context with macro environments influencing micro environments, which in turn have effects on children's development.

Poverty and social position in society, war, and exposure to violence in neighborhoods have all been shown to have influences on the development of child psychopathology. Some of this influence operates indirectly through the proximal environment (children's relationships), while some of the effect is direct to the child. Children's relationships with parents, peers, and siblings as well as their exposure to marital conflict are more negative and problematic, the more negative and problematic the macro-context. When these relationships are problematic, children show higher levels of disorder. Understanding the mechanism in this association is complex, however, as child characteristics influence children's experiences in family relationships and who they befriend. Finally, it is very important to recognize that the vulnerability of children to environmental stressors varies enormously, an issue discussed in Chapter 27.

Directions for future research

One of the most significant issues in this area is the extent to which proximal adversities such as parenting, peer, and sibling influences are independent of the individual. Designs that examine behavior over time or across interactional partners are helpful for improving our understanding of this issue. Second, issues related to the timing and sequence of risk exposure, as well as the vulnerability of individuals to timing and sequence, will become increasingly important as we gain a better understanding of biological embedding. Third, there have been successful randomized control trials related to reducing children's exposure to environmental adversities and thus improving behavioral outcomes. It would be valuable to combine these with measurement of brain structures and neuroendocrine and immune function in order to examine the extent to which these biological processes mediate the relationship between exposure to adversity and child behavior (see Chapter 25).

CHAPTER 27

Resilience: concepts, findings, and clinical implications*

Michael Rutter

Institute of Psychiatry, Psychology & Neuroscience, King's College London, UK

Resilience, as used in this chapter, is a concept that brings together three essential features (Garmezy *et al.*, 1984; Garmezy & Tellegen, 1984; Rutter, 1987; Luthar, 2003). First, it can only be studied in individuals who have experienced significant adversity. Second, there is heterogeneity in outcome, with a resilience pattern being present when the individual is functioning much better than others who have experienced the same degree and type of adversity. Third, the resilience pattern is inferred from evidence of the relatively better outcome; that is, it is not a trait that can be measured directly. Also, a resilience pattern rarely operates in a categorical pattern. That means that it is seriously misleading to use the term “invulnerability” (as put forward by Anthony, 1974; Anthony & Cohler, 1987). A resilience pattern may be evident with respect to some types of adversity but not others. Thus, it should not be expected that resilience in relation to psychosocial hazards will also apply to infections or carcinogenesis. Similarly, it may be present at one developmental period but not others. Although resilience patterns are likely to show significant temporal stability, they can change markedly if social circumstances alter. For all these reasons, Luthar and Zelazo (2003) urged that it is best to avoid terms such as “resiliency” that imply a personality trait, that resilience should apply to patterns and not individuals, and that the concept should refer to a *process*.

Nevertheless, it has to be accepted that not everyone agrees. For some, the roots of resilience as a concept lie in the emergence of positive psychology (Seligman & Csikszentmihalyi, 2000) and the wish to emphasize the positive rather than the maladaptive (Mohaupt, 2009). A helpful aspect of this movement was the wish to urge that socioemotional well-being (including a sense of purpose) was as important as economic

success (Keyes, 2007). An unhelpful aspect was a downgrading of the seriousness of mental disorder in order to concentrate on variations in the degrees of happiness in the general population (Layard, 2005), as well as an ignoring of the methodological problems inherent in the concept of “positive mental health” (Jahoda, 1959) and the difficulties in differentiating between hedonic pleasure and excitement and the quiet satisfaction of a job well done (Rutter, 2011).

An alternative starting point is provided by the concept of psychosocial competence (Masten *et al.*, 1999). It has all the advantages of using a desirable quantifiable outcome, but it suffers from four important limitations. First, it implies that the causal influences will be much the same in nonstressed groups as in those suffering extreme adversity, with nonlinear effects (meaning those that vary across the span of outcomes) identifiable only through mathematical modeling (see, e.g., Maier *et al.*, 2012) with uncertainties involved in the assumptions required (Parker & Maestripieri, 2011; Seery, 2011). Second, it implies that outcome will ordinarily be identifiable on the balance between risk and protective factors, with both identifiable on the basis of their *nature* rather than their effects. Third, it assumes that most individuals will respond to stress and adversity in much the same way and to the same degree. Fourth, it assumes that competence can and should be measured in an absolute way rather than in terms of functioning that is unusually positive in relation to the adversities experienced.

The starting point for the concept of resilience is quite different. Rather than make untested assumptions, it begins with the extensive empirical evidence that there is enormous heterogeneity in people's responses to all manner of stresses and adversities (Rutter, 2006). Because of the evidence that resilience needs to incorporate recovery (partial or total) from earlier adversity and not just to good outcome despite current adversity, a life-course perspective is required. This indicates the

* This chapter is largely based on two papers by the author: Rutter (2012b, 2013a).

likelihood of a dynamic process rather than some “chemistry of the moment” effect operating at just one moment in time.

For all these reasons, resilience is quite different from positive psychology and from psychosocial competence. Both gave rise to findings that indicate beneficial effects of features that operate similarly across the population. They are most important both scientifically and clinically but to avoid the misleading implication that they are protecting against some risk, the term “promotive” factors should be used (Sameroff *et al.*, 2003; Luthar & Zelazo, 2003). But, how is resilience research different from traditional risk and protective factors research? To begin with, it is the same with respect to the essential need to determine risk and protective effects in order to go on to investigate individual differences in outcome. That is, to a considerable extent, variations in outcome *are* a function of individual differences in exposure to risk and protective influences (Sameroff *et al.*, 2003). Resilience is concerned only with the differences (albeit large differences) that remain *after* risk and protective factor variations have been taken into account. In short, resilience research has to begin with a careful study of risk and protective influences.

There are 10 main features that serve to characterize resilience research as different from the overall field of risk and protective factors research (Rutter, 2012b). First, there is a *direct* analysis of the features associated with heterogeneity rather than a reliance on statistical analyses to detect nonlinear interactive effects. Gene–environment interactions ($G \times E$) research starts with the explicit expectation that environmental hazards will *not* have the same effect in everyone, and that genetic features may account for the individual differences.

Second, there is a requirement to test for environmental mediation of risk effects (Rutter, 2007, 2012a). It might be supposed that should apply equally to risk research, and indeed it should, but in fact most psychosocial researchers have ignored this need (Rutter, 2012a).

Third, there is an interest in variables that are without effects in the general population of low-risk individuals, but which have substantial effects in the presence of adversity. Adoption is the obvious example of this kind (Rutter & Sonuga-Barke, 2010; Rutter *et al.*, 2012). Adoption is not a particularly beneficial experience in the general population but it may be *very* protective for individuals experiencing abuse or neglect in their biological family.

Fourth, resilience requires an interest in the possible “steeling” or strengthening effects of coping successfully with stress or challenge. That is, it involves an interest in and focus on negative experiences that may nevertheless provide a protection against later stressors. That requires a focused hypothesis-testing approach—a feature of resilience research but not of risk research to the same extent.

Fifth, a specific example of hypothesis-driven research is that undertaken to study gene–environment interaction ($G \times E$) (Rutter *et al.*, 2009; Rutter, 2014). A further key characteristic is the explicit acceptance that epidemiological approaches have

to be put to the test through experimental studies, and basic science (see Rutter, 2014).

Sixth, in resilience research, animal models constitute a key element in the research strategy (see later). The study of stress inoculation in squirrel monkeys provides a good example, in that it focused specifically on possible steeling effects and used an experimental approach (Parker *et al.*, 2004). There is absolutely no reason why this should not be done with risk research but it has rarely been done.

Seventh, resilience includes a study of possible turning point effects, such as evident in the beneficial effects of marriage (Sampson *et al.*, 2006) and of early service in the Armed Forces for individuals from a disadvantaged background (Sampson & Laub, 1996).

Eighth, a key feature of resilience research has been the use of qualitative data to determine the *meaning* of experiences—a crucial detail in understanding *how* resilience might come about. This is evident in the study of positive outcomes in young people hospitalized for mental disorders in adolescence (Hauser *et al.*, 2006), and Laub *et al.*’s (1998) study of the protective effects of marriage. Note that in both cases, qualitative and quantitative data were considered together. It is a major error to consider qualitative and quantitative research as competing opposites (Rutter, 2013b).

Ninth, there are the basic findings on brain plasticity (Hensch, 2005; Bavelier *et al.*, 2010; Rutter, 2012a) which underline the dynamic concept of brain changes in terms of their temporal limits and the openness to external influences (see Chapter 23).

Finally, resilience is defined in terms of a better outcome than that usually seen in other individuals from a similarly adverse background. That is, there is no requirement of functioning that is superior to the nondeprived population as a whole. The study of Romanian adoptees (Rutter & Sonuga-Barke, 2010; Rutter *et al.*, 2012) illustrates the point. A minority of individuals had superior outcomes in relation to the general population, but a large proportion did remarkably well in relation to the other adoptees who experienced profound institutional deprivation, although they were not generally superior in functioning to nondeprived individuals. Resilience is an interactive concept and hence what matters is the variation in response among individuals experiencing the same level and type of adversity.

Testing for environmental mediation of risks

Before considering the “natural experiment” strategies designed to test environmental risk mediation, it is necessary to consider the several reasons why a statistical association might not reflect causation (see Chapter 12 for a more detailed critique). First, the relevant aspect of an overall environmental risk situation may have been misidentified. For example, for many years, family breakup was viewed as a causal risk factor for antisocial behavior in the children. Fergusson *et al.* (1992), by statistically contrasting breakup with family discord/conflict, showed that

the main risk stemmed from the latter. The implication was that resilience would have to be investigated in relation to discord/conflict rather than family breakup.

Second, the causal influence might be genetically mediated in part. Most risk effects stem from people's behavior rather than acts of fate. Thus, this would apply to physical abuse. In this case, twin analyses showed that abuse was largely environmentally mediated, whereas physical punishment was more often reactive to the child's behavior (Jaffee *et al.*, 2004). Resilience could reasonably be studied in relation to abuse but it would be problematic in the case of physical punishment because it carried such a minor environmentally mediated risk.

Third, the exposure to the risk situation might be a consequence of choice or social selection. For example, it has long been observed that members of delinquent gangs commit a large number of crimes. But, is this because of the characteristics of the individuals who join such gangs, or is it the result of an influence from the gang? Thornberry's longitudinal study (Thornberry *et al.*, 1993) showed that both applied but there was a significant tendency for more crimes to be committed while people were gang members. One of the ways in which social selection effects may be bypassed is by focusing on circumstances when *whole* populations were subject to some experience without the opportunity to exercise choice. The World War II Dutch famine (Stein *et al.*, 1975) and the somewhat comparable Chinese famine (St Clair *et al.*, 2005) provide examples in relation to the risks of schizophrenia associated with prenatal famine—because the famine affected the total population. The Casino study by Costello *et al.* (Costello *et al.*, 2003) did the same with respect to the effects of relieving poverty, and the Japanese cessation of using the MMR (measles, mumps and rubella) vaccine (Honda *et al.*, 2005) showed that MMR was not responsible for an “epidemic” of autism. Atladóttir *et al.* (2007) had the same negative findings with respect to the hypothesis that Thimerosal supposedly also had given rise to an epidemic of autism. The opportunity arose because Scandinavia ceased using this mercury preservative at a time when widespread usage was continuing in the rest of the world.

Types of features associated with resilience

A wide range of features have been described as ones fostering resilience (Luthar, 2003; Ungar, 2012) but an understanding of resilience may be more usefully aided by focusing on the key *types* of features associated with resilience, starting with those that do not fit easily into a standard risk model.

Features that are neutral or risky in the absence of a risk experience

The search for such features is predicated on the basis that risk and protection must be measured with respect to their *effects*, rather than appearing inherently negative or positive in nature. The best known medical example is heterozygote sickle cell status, which provides a substantial protective effect

against malaria, despite the fact that homozygote status leads to the very serious sickle cell disease (Aidoo *et al.*, 2002). A possible psychological equivalent may be adoption or long-term fostering, although this provides protection through an entirely different mechanism (namely, the provision of a new rearing environment that replaces, and is superior to, the abusive or neglectful environment that constituted the initial risk). It is not that adoption is always preferable to being reared by biological parents. Indeed, because adoption constitutes an atypical experience, it may involve a very slight psychopathological risk. On the other hand, the adoption of a child who has been reared in a profoundly depriving institutional environment (see Nelson *et al.*, 2007; Rutter & Sonuga-Barke, 2010; Rutter *et al.*, 2012), or who has been removed from parental care because of serious abuse or neglect (Duyme *et al.*, 1999), will lead to improved psychological functioning. This has been shown by group comparisons (as part of a randomized controlled trial) of children left in an institution versus those provided with good quality long-term fostering (see Nelson *et al.*, 2007; Fox *et al.*, 2011). It has also been demonstrated by the within-individual change over time of children who leave institutional care to move to an adoptive home (Vorria *et al.*, 2006; Rutter & Sonuga-Barke, 2010; Rutter *et al.*, 2012).

Nonmaternal care constitutes a different, but somewhat comparable, example. There is no reason to suppose that being cared for by someone other than the biological mother constitutes a generally beneficial experience if the care provided by the biological mother is good. Nevertheless, two Canadian studies have shown that nonmaternal care is associated with worthwhile benefits for children from disadvantaged families (Geoffroy *et al.*, 2007; Côté *et al.*, 2008). In short, the key question in each case is not whether some supposedly atypical rearing environment constitutes an unusual health-promoting experience, but rather whether it improves upon what the child would have had in the risky environment. When it does, it will foster better functioning than the child would have had being reared by the biological mother.

Mental features

Both quantitative and qualitative research have pointed to the role of mental features in resilience. Thus, Clausen (1993, 1991) referred to the importance of planfulness in overcoming adversity and disadvantage, and Quinton and Rutter (1988), in their study of institution-reared girls found that planning was important in key life decisions (Quinton *et al.*, 1993). It was not any particular planning skill that was crucial but, rather, the self-concept that they could have some control over their lives and hence could, and would, take active decisions instead of just assuming that they were at the mercy of other people's actions.

Two points are fundamental in thinking about these findings in relation to resilience. First, the empirical findings showed that neither planning with respect to choice of marriage partner nor choice of employment were influential in girls being reared in a low-risk environment. That is because their peer group

was largely neither disadvantaged nor deviant. If they selected a marriage partner by random allocation, they were likely to choose one who was relatively well-functioning. Clearly, that was not at all the case with the institution-reared girls whose peers were mainly similar to themselves. Thus, there was an interaction effect. Second, it appeared that the main influence on planning derived from successes in some activity at school (the one other operative environment they experienced). Scarcely any girls had gained any kind of scholastic achievements but some had successes in music or sport on in gaining some position of responsibility. It seemed that the ability to exert control in one area of their life made it more likely that they would develop a positive self-concept and, most crucially, a cognitive set that they could and would deal successfully with life experiences. Also, Bandura (1995) has shown that what he called “self-efficacy” was more important than simply feeling good about yourself.

Hauser *et al.* (2006) undertook qualitative interviewing comparing young people who fared unusually well (as shown by quantitative analyses) despite a period of psychiatric institutional care in adolescence, as against those with an average outcome. Three main features were identified: (1) a style of self-reflection to assess what had worked or not worked for them; (2) a sense of agency or determination to deal with challenges (meaning *actions* to deal with the issues) and a self-confidence in being able to do so successfully (equivalent to Bandura’s self-efficacy), and (3) a commitment to social relationships.

Moffitt *et al.* (2011), in the Dunedin longitudinal study, found that good self-control in childhood was associated with better health and social psychological outcomes. The effects were independent of IQ and social class and operated dimensionally across the population. The research included no intervention but the finding that improvements over time in self-control were associated with better outcomes suggested a probable causal effect. While this cannot be definitely considered as a resilience feature in the absence of a demonstrated interaction, it seems possible that this is also one component of mental features associated with resilience.

Turning points in life after childhood

Much of the literature on resilience focuses on the childhood years, but the evidence of positive turning points in adult life argues for the need for a life-course perspective. Two well-studied naturalistic examples from Sampson and Laub’s long-term follow-up of the Gluecks’ sample of incarcerated male delinquents serve to illustrate the point (Sampson & Laub, 1993; Laub *et al.*, 1998; Laub & Sampson, 2003). First, it was found that men who married had a better outcome; the difference remaining after controlling for a range of possibly relevant confounding variables. They went on to test this further through examination of within-individual change across periods of being and not being married, capitalizing on the natural experiment provided by the rather high rate of marriage breakdown and remarriage in

American society. They created a propensity score based on the 20 variables that best predicted whether individuals would get married. This was then used, in effect, to create groups matched on their propensity scores. The overall changes in crime rate according to age were then put into the model before examining crime variation according to whether the individual was or was not married. The findings showed an overall reduction of 36–43% in crime rate during periods of marriage—confirming the protective effect of marriage.

For this finding to be clinically useful, it was essential to determine what it was about marriage that brought about this effect. John Laub tackled this question by means of systematic qualitative interviews of a purposive sample of 52 of the men. The findings indicated that marriage had many facets. These included, as one might expect, a loving supportive relationship but it also included the regulating function of wives with respect to both employment and family activities, in turn associated with the acquisition of a new kinship group and new peer group. The crucial features seem to be the “knifing off” of the past, and the opening up of fresh opportunities for the future (Maruna & Roy, 2007). Of course, people varied in the extent to which they made good use of the opportunities that were available—the mental features already discussed probably playing a key role in this connection. There is a parallel in Costello *et al.*’s (2003) finding on the relief of poverty brought about by the distribution on an Indian reservation of casino proceeds—as required by US federal law. Not surprisingly, families varied in the extent (and way) to which use was made of the increase in income. Interviews suggested that the mediation might lie in an increased amount of parenting time with the children, accompanied by greater supervision.

The second example is provided by early service in the Armed Forces for individuals from a severely socially disadvantaged background at the time of the 1930s Great Economic Depression (Elder, 1986). Sampson and Laub (1996) showed that such Armed Services experiences were associated with significantly better outcomes as compared with individuals from a similar background who did not serve in the Armed Forces. This was a resilience effect, as evidenced by the finding that the benefits did not apply to individuals from a nondisadvantaged background. The key question was why and how the potentially stressful experience of Army service served to provide protection. It should be appreciated that serving in the Army at that time did not involve the very high risk of death and mutilation associated with recent experiences in Iraq and Afghanistan.

As with marriage, it turned out that Army service was multifaceted. Probably, two key features mattered most. First, most of the young men had dropped out of school and lacked scholastic qualifications. Education in the more “adult” arena of the Armed Forces re-engaged many with the consequent benefits of both enjoyable learning and the acquisition of qualifications. The Government Issue (GI) bill also provided funding for a later college education. Postponement of marriage constituted the second advantageous feature. Not only did it mean that

marriage could take place after, rather than before, a career was established but also it opened up the pool of potential marriage partners beyond the group of similarly disadvantaged, and often delinquent, young people that constituted their peer group prior to Army service. The data did not allow determination of just which elements in the experiences were crucial but they did point to a likely chain of events and experiences that involved both a “knifing off” of the past and the provision of new opportunities. It is highly probable that mental features influenced the extent to which such opportunities were actually taken up and made good use of. However, although the quantitative findings provide strong evidence of a resilience effect from both marriage and Army service, the precise operative elements in resilience remain speculative (but they could, and should, be tested).

Enhancement of successful coping with stress/challenge

It might be assumed that the avoidance of all environmental hazards is always desirable but, in fact, this is not the case. This is evident from the medical example of the need to be *exposed* to infectious agents in order to acquire immunity from the infectious diseases that they bring about. The problems that arise from *lack* of exposure is well illustrated by the way in which the individuals evacuated to the United Kingdom from Tristan de Cunha following a volcanic eruption there, succumbed to measles, influenza, and the like to which they had not developed immunity (Tyrrell *et al.*, 1967). Immunization represents the protection provided by the induced exposure to a modified version of the pathogen. Incidentally, the development of immunization against smallpox arose from Edward Jenner’s astute observation that people exposed to cowpox (an infectious agent similar to smallpox but much milder in the effects) were much less likely to develop smallpox.

In addition, there is evidence that exposure to microbacterial agents is protective against some forms of atopic disease—particularly asthma. Children reared on farms are less likely to get asthma because of the endotoxins to which they are exposed; marked hygiene seems to increase the risk (Strachan, 1989; von Mutius, 2007; Martinez, 2008; Obihara & Bardin, 2008).

A psychopathological parallel is possibly provided by the treatment of specific phobias (Marks, 1987; Rachman, 1990). It appears that *avoidance* of the feared object makes it particularly likely that the phobia will persist. Various forms of behavioral treatment have been shown to be effective but all involve some type of controlled exposure that leads to successful coping with encounters with the feared object.

Another possible example is evident in the naturalistic, non-experimental, observations by Stacey *et al.* (1970) that children who experienced happy separations from their parents (such as by sleepovers or staying with relatives) were better able to cope with the more complicated multiple stresses associated with hospital admission.

Glen Elder (1974) found that adolescents who had to take on additional family responsibilities during the Great Economic Depression of the 1940s, and who coped successfully with those responsibilities, often seemed strengthened by what they had to do. By contrast, this was not evident with younger children who appeared less able to cope with what was demanded of them. Of course, taking on unusual responsibilities should not be viewed as a psychological “pathogen,” but it does seem that coping successfully with either stresses or challenges may be strengthening or “steeling.”

The most convincing evidence of “steeling” effects of controlled exposure is provided by the squirrel monkey studies undertaken by David Lyons and his colleagues (Parker *et al.*, 2004; Lyons & Parker, 2007; Lyons *et al.*, 2009; Lyons *et al.*, 2010)—building on the early studies by Levine in the early 1960s and continued up to the time of his death (Levine & Mody, 2003).

In brief, they used a strategy that mimicked the normal tendency in nature for the occurrence of brief mother–infant separations brought about by the mothers going off to forage for food when the newly weaned infants reached 3–6 months of age. Socially housed squirrel monkeys were randomized at 17 weeks of age to either brief intermittent separations for a one-hour period once each week for a total of 10 weeks or a nonseparated control condition. After 27 weeks of age, both groups were reared in identical conditions. Behavioral, hormonal, and brain imaging data were obtained at specified ages up to adulthood.

At 9 months in a novel environment test, the two groups were initially similar but they became more different over repeated sessions. Cognitive control was assessed at 2½ years. On all these measures, the separated group performed better and cortisol measures showed a decreased reactivity to stress. Neuroimaging showed that the separated monkeys had a larger ventromedial prefrontal cortex volume. Other experiments showed that the changes in arousal more closely corresponded to stress exposure than to separation-induced changes in maternal care.

Similar beneficial effects of *brief* exposure were found in rats but prolonged separation led to increased *sensitization* to later stress experiences, rather than steeling. The overall body of evidence from animal models suggests the reality of steeling effects from brief stress experiences that are not accompanied by overall adversity or deprivation. Rather than focus on the precise level of stress that can provide protection, it is probably preferable to focus on whether or not stress or challenge leads to effective physiological and psychological coping. Of course, that dodges the difficulties in defining and measuring coping but, nevertheless, that does seem the most appropriate focus.

Gene–environment interactions (G × E)

From the outset, studies of maternal deprivation, and other forms of family adversity, indicated the huge variation in children’s responses to apparently comparable experiences. Rutter (1972) suggested that one element influencing this heterogeneity

might lie in genetic influences on environment susceptibility. This would mean some form of gene–environment interaction ($G \times E$).

Quantitative behavioral genetic studies provided many pointers to the likely occurrence of $G \times E$ —especially with respect to the outcomes of depression and antisocial behavior (Rutter & Silberg, 2002). However, this early evidence was severely limited by the necessity of having to deal with “anonymous” genes. The situation became transformed by the availability of molecular genetic methods to identify individual genes and by the greater availability of measures of specific environments with a tested environmental mediation of risk (Moffitt, 2005; Rutter, 2014).

The leadership in the field of epidemiological/longitudinal studies of $G \times E$ was undoubtedly provided by the Dunedin studies undertaken by Caspi, Moffitt, and their colleagues, using the Dunedin longitudinal study. They started with reports using polymorphic variants of the MAOA gene (Caspi *et al.*, 2002) and the serotonin transporter (5HTT) promoter genevariant (Caspi *et al.*, 2003). The environmental hazards studied included both maltreatment in early childhood and stressful life events in adolescence. The focus of the mistaken critique of $G \times E$ had been solely on stress (Risch *et al.*, 2009) but, not only is maltreatment the greater hazard but also a large-scale meta-analysis of a range of adverse experiences (Karg *et al.*, 2011) showed that there was only marginal statistical significance for $G \times E$ dealing with stressful life events but a much larger, highly significant $G \times E$ with respect to maltreatment.

Figure 27.1 uses the 5HTT interaction with maltreatment to illustrate what is meant by an interaction. The upper green line shows a strong effect of maltreatment in those who have two copies of the short allele, whereas the bottom line shows no effect of maltreatment in those with two copies of the long allele. The Risch *et al.* (2009) paper created a stir in its challenge to the validity of $G \times E$. However, it was based on a biased sample and it paid no attention to measurement issues (Uher & McGuffin, 2010). Also, it failed to pay attention to nonepidemiological research strategies (Caspi *et al.*, 2010).

With respect to maltreatment, the findings were striking in showing that the psychopathological sequelae of depression and antisocial behavior were minimal in the case of one particular genotype and much greater in the case of other genotypes. In other words, one genetic variant was associated with a resilience pattern following an experience known to carry a major mental health risk. Four findings are particularly important with respect to resilience. First, the $G \times E$ effects are largely specific to a narrow range of outcomes. Thus, the MAOA genotype showed a resilience effect in relation to antisocial behavior but no such effect in relation to depression. Similarly, the 5HTT genotype showed a resilience effect with respect to depression but not at all in relation to antisocial behavior. The findings underline the implausibility of there being a generalized resilience trait. Second, the Karg *et al.* (2011) meta-analysis findings pointed to the likelihood of a biological process that extended over a long time period extending from early childhood into early adult

Figure 27.1 Effects of maltreatment on liability to depression moderated by the 5HTT gene (based on Caspi *et al.*, 2003). Source: Reprinted with permission of American Association for the Advancement of Science.

life—rather than one concerned with an immediate effect that involved a protection against the provoking of an onset of some mental disorder. Third, the human experimental studies of Weinberger, Hariri, and Meyer-Lindenberg (Meyer-Lindenberg & Weinberger, 2006; Hyde *et al.*, 2011) examining the neural effects of $G \times E$ as studied by brain imaging, showed that the $G \times E$ applied to individuals *without* psychopathology. In other words, although the $G \times E$ is relevant to disorder, it concerns processes that apply to all of us. Fourth, there is extensive evidence from animal models confirming the operation of $G \times E$ in relation to comparable genes to those operative in humans (Rutter, 2014).

The evidence available to date does not identify the precise mediating mechanisms for these resilience effects but the implication is that the existence of $G \times E$ is likely to mean that either the genetic and environmental influences operate on the same biological pathway or that the two pathways are close together. That possibility requires systematic testing because of the potential of determining how both G and E operate. From a practical point of view, it will also matter whether the genes affect susceptibility to adverse environments only or susceptibility to all environments. Evolutionary considerations and a growing amount of empirical evidence suggest that the latter is probably the case (Ellis *et al.*, 2011), although there may be some domain specificity (Obradović *et al.*, 2011; Essex *et al.*, 2013). The clinical implication is that the genetic polymorphisms associated with vulnerability to adverse environments may also be associated with greater responsivity to positive environments brought about through therapeutic interventions.

Supportive family warmth and cohesion

Humans are social beings and it might therefore be expected that the presence of supportive family relationships might

aid resilience. Bowes *et al.* (2010) investigated this possibility using the UK Environmental Risk (E-Risk) prospective longitudinal study—focusing on the possible protective role of family warmth and positive family atmosphere in buffering the damaging effects of bullying victimization (shown through the twin design to be environmentally mediated). These positive family features assessed when the children were aged 5 and 10 years were significantly protective against the effects of bullying on emotional and behavioral disturbance at 10 and 12 years. The benefits were also evident in nonbullied children (indicating a promotive rather than a resilience effect) but a significant interaction with bullying indicated that they were greater in the bullied (indicating a resilience as well as a promotive effect). A discordant MZ twin strategy was used to test whether the beneficial effect of maternal warmth was environmentally mediated—finding that it was in the case of behavioral problems.

Overview of resilience features

By focusing on features that account for variations in the response to adversity, rather than risk/protective factors in the total population, resilience research has identified several different sorts of features that would have been less easily identified in traditional risk/protective factor analyses. The features identified included (1) features (such as adoption) that were neutral or risky in the absence of a risk experience; (2) mental features such as planfulness and self-efficacy; (3) beneficial turning point experiences in adult life such as marriage or service in the Armed Forces; (4) successful coping with stress/challenge (as brought about by exposure to the environmental hazard or challenge) and (5) gene–environment interaction. In addition, warm family support was found to have both promotive and resilience effects.

Clinical implications

There are six key conceptual considerations that need to guide all clinical implications of resilience findings. First, when resources are limited it makes sense to focus on those in greater need—those experiencing the chronic adversities considered in resilience patterns. Second, resilience findings have identified key causal influences that had not emerged from research into risk and protective factors (see later). Third, because some variable describes an environmental feature (such as poverty or social disadvantage), that does not mean that the psychopathological risks are environmentally mediated. At least some part of the effects may be genetically mediated, or represent reverse causation or bidirectional effects (see Chapter 12). Fourth, many influences are relatively context-specific (see Rutter, 1999), making it mandatory to consider the likely impact in each individual case. The findings on family breakup, marriage, and nonmaternal care well illustrate the point (see British Academy Working Group Report, 2010; Rutter, 2013a). Fifth, resilience operates as

a dynamic process across the lifespan, with restorative as well as protective effects. Sixth, the mediating mechanisms involved in resilience patterns may involve the biology (as shown, e.g., by $G \times E$), as well as mental operations (see Chapter 23).

Prevention

Although there have been programs designed to teach resilience (Ungar, 2012), these have a dubious validity because resilience is not a characteristic that can be taught or measured; it is an interactive concept that can only be identified in terms of the response to some adversity. On the other hand, it is appropriate to consider what can be done to provide individuals with the competencies that might make them better prepared to deal with adversity when it occurs.

First, in prevention, attention should be paid to the role of mental features such as planning, self-reflection, and active personal agency. Under the rubric of self-efficacy, Bandura (1995) has shown how this may be taught through experiential teaching (rather than didactic instruction), with demonstrated efficacy.

Second, there should be a focus in schools on the value of children taking responsibility, exercising a degree of autonomy, and having the opportunity of learning from their mistakes. Schools that do this well have been shown to have better pupil outcomes (Rutter *et al.*, 1979; Rutter & Maughan, 2002). More specifically, some schools have schemes to teach children how to deal with peer conflict in the classroom or playground by becoming peer mediators (Johnson & Johnson, 1996). The prime goal of such schemes is not the teaching of resilience in relation to children's own experiences but that is likely to be a worthwhile by-product.

Third, it should be worthwhile to take actions on the basis of the evidence of the protective effects of being exposed to and coping successfully with challenges and stresses. This means that children should be expected to be exposed to manageable risks, challenges, and responsibilities rather than being protected from the need to cope with them.

Fourth, attention should be paid to the value of adoption or long-term fostering when child abuse or neglect or serious parental problems have led to the child being removed from the care of the biological parents. A series of short-term foster care placements without any decision or action on long-term plans is not in the child's interest. On the other hand, adoption without the approval of the biological parents would not be ethically acceptable unless strenuous, well-focused efforts have been taken to determine whether the parents could be helped to cope effectively with their problems. This dilemma is particularly acute in the case of newborn babies being removed at birth on the basis of the severe risks associated with the mother's drug or alcohol problems. A novel initiative was set up, with the support of the Coram Foundation, in which remedial intervention was provided for a 6-month period after which a decision had to be taken on whether sufficient progress had been made to justify leaving the child in the care of the biological parents (with whatever further intervention seemed required) or, recognizing that adequate care was unlikely to be attainable, adoption should

be made available without further procrastination (Harwin *et al.*, 2011). A further follow-up has been undertaken with the support of the Nuffield Foundation.

Fifth, possible turning point experiences after childhood need to be considered in terms of when they may make possible the “knifing off” of the adversities of the past and the provision of new opportunities for success and good relationships. Clearly, it is not practicable to prescribe good marriages (or other experiences) but it would be feasible to consider how such experiences may be guided or shaped to enable them to be most likely to provide a positive turning point.

Sixth, the findings on the resilience, as well as promotive, benefits of good warm family relationships indicate that therapeutic interventions designed to reduce family conflict and hostility and intervention to improve parenting, although not targeted on resilience, are likely to have resilience benefits (Bowes *et al.*, 2010).

Finally, the evidence on $G \times E$ draws attention to the potential value of paying attention to the biological pathways involved. At the moment, because the mechanism remains poorly understood there are no specific treatment pointers but they are likely to become available in the future. Although certainly not indicated at the moment, the treatment pointer might indicate a possible pharmacological intervention.

Treatment

Resilience concepts and findings do not point to a specific type of treatment but, nevertheless, they do have major implications for what is needed in any clinical assessment. Thus, the substantial evidence that there is huge heterogeneity in people's responses to all manner of environmental hazards means that, in addition to diagnosis, assessment must include an analysis of possible causal influences in that individual and a consideration of the mechanisms by which they might have operated. The focus must be on the present at least as much as on the past. Thus, there should be an appraisal of features in the child, or in the family and social circumstances, that provide either continuing risk or possible protection. This appraisal has to take account of social context because the context may alter the meaning of experiences (Rutter, 1999). There are four basic messages in considering positive or negative causal influences. First, attention needs to be focused on those for which there is good evidence of environmental mediation of effects. Second, some influences may have begun in early childhood but nevertheless have effects that persist even into adult life (Rutter & Sonuga-Barke, 2010; Karg *et al.*, 2011). Third, although acute negative life events may provoke the onset of a disorder, the long-term effects of chronic adversity tend to be much greater than those of acute events. Fourth, when considering the sequelae of early adversity, there needs to be attention to possible turning point experiences. Could there be a possibility of changing circumstances so that there might be some experience that both “knifed off” the past and provided new opportunities for success and good relationships. For example, are there youth

groups that could build on the individual's strengths? Could the school provide appropriate opportunities? Would it be helpful to seek the involvement of other family members? Does the individual's history provide clues on escape from, or successful coping with, past adversities or difficulties? How did the child (and family) deal with past crises or challenges, as success then may be relevant for the present situation? Sibling comparisons may also be informative in providing clues to possible coping strategies.

Resilience findings, both quantitative and qualitative, emphasize the importance of mental phenomena—ideas, attributes, self-reflection, and planning. Any adequate clinical assessment should assess these with an interest in those that might have the potential for overcoming adversity. In that connection, whatever treatment is implemented—whether psychological or pharmacological—it will be crucial to ensure that it is provided in a manner that encourages patients to consider that they can “act” to improve their situation, rather than feel that all benefits derive from what the clinician does. The goal of all treatments must be to pass the initiative back to the patient and so avoid a dependent reliance on the therapist. Attention also needs to be paid to the child's ongoing relationships; successful coping encompasses the social, as well as the psychological, dimension.

Conclusions

Resilience concepts and findings should be making an impact on clinical practice. It is a dynamic concept concerned with process rather than traits and it focuses attention on experiences that can foster improved coping. Such experiences are not necessarily unambiguously positive in appearance because the benefits may come from coping successfully with challenges and manageable stressors; from experiences that are neutral, or even slightly risky, in the absence of adversity; from experiences that provide fresh opportunities and a distancing from past troubles, from mental phenomena such as planning, self-reflection, and self-efficacy; and from biological pathways that bring together genes and environment in a biological pathway that extends over a long time period. Resilience is not an individual characteristic that can be taught but it should be possible through experiential influences to enable young people to be able to develop a style of functioning that will make resilience more likely.

CHAPTER 28

Impact of parental psychiatric disorder and physical illness

Alan Stein¹ and Gordon Harold²

¹Department of Psychiatry, Child and Adolescent Psychiatry, Warneford Hospital, University of Oxford, UK

²Rudd Centre for Adoption Research and Practice, School of Psychology, University of Sussex, Brighton, UK

There is a substantial body of evidence that psychiatric and physical disorders in parents are associated with an increased rate of psychological disturbances in children. However, contemporary research evidence is illuminating the mechanisms through which some children experience elevated psychological disturbances in response to parental psychiatric disorder, while other children show resilience to such intergenerational transmission. The elucidation of the mechanisms involved in the intergenerational transmission of disorder is scientifically important in helping to understand the pathways to both healthy and disturbed development, and informative in developing interventions aimed at reducing the intergenerational transmission of psychopathology to children.

Intergenerational transmission of psychiatric disorder: a conceptual and theoretical overview

One of the most consistent correlates of psychiatric dysfunction is having a parent with a history of psychiatric disorder. Offspring of depressed parents, for example, are at least three times more likely to develop a mood disorder as well as other psychiatric problems and impairment compared to children of nondepressed parents (Weissman *et al.*, 1997). The intergenerational transmission of psychiatric disorders is a complex and multifaceted process (Serbin *et al.*, 2004).

Specifically relating to depression, for example, Goodman and Gotlib (1999) proposed four general explanations for the transmission of depression from mothers to children: heritability; innate neuroregulatory dysfunction; exposure to maternal negative affect, cognitions, and behaviors; and increased stress in the family (see Garber *et al.*, 2010). We offer an integrated

theoretical model that conveys the complex and multifaceted processes through which early exposure to parental psychiatric disorder may confer developmental risk to children (see Figure 28.1). In this figure, parental psychiatric disorder is presented as an early risk factor that sets the stage for a cascade of processes through which elevated risk for offspring psychopathology is conveyed.

Contemporary research models have moved beyond examining simple bivariate associations between specific risks and related risk outcomes, to examining the pathways and processes through which early parental risk may confer elevated risk outcomes for children. Specifically, factors that mediate and moderate initial associations are examined as mechanisms through which risk effects are conveyed, and thus offer sites through which intervention targets may be directed in order to reduce or ameliorate the intergenerational transmission of risk outcomes. For example, parental depression has been linked to disruptions in children's neurobiological functioning (e.g., HPA axis dysregulation), cognitive-emotional-social processing (e.g., negative attributions, emotional regulation, social skills), as well as disrupted patterns of family functioning (e.g., heightened interparental conflict, negative parent-child relationships). These, in turn, could link to elevated symptoms of depression in children. While each of these theoretical domains offers a mediating process through which associations between parental depression and child depression may be explained (see Figure 28.1, e.g., Paths E + I; Paths F + J; Paths M + N), each intervening domain may also offer further mediation (e.g., G + K; L + H). One possible explanatory sequence underlying the intergenerational transmission of psychopathology may emanate from early psychiatric risk leading to dysregulated neurobiological functioning, which in turn disrupts cognitive, emotional and social processing, offering the propensity to

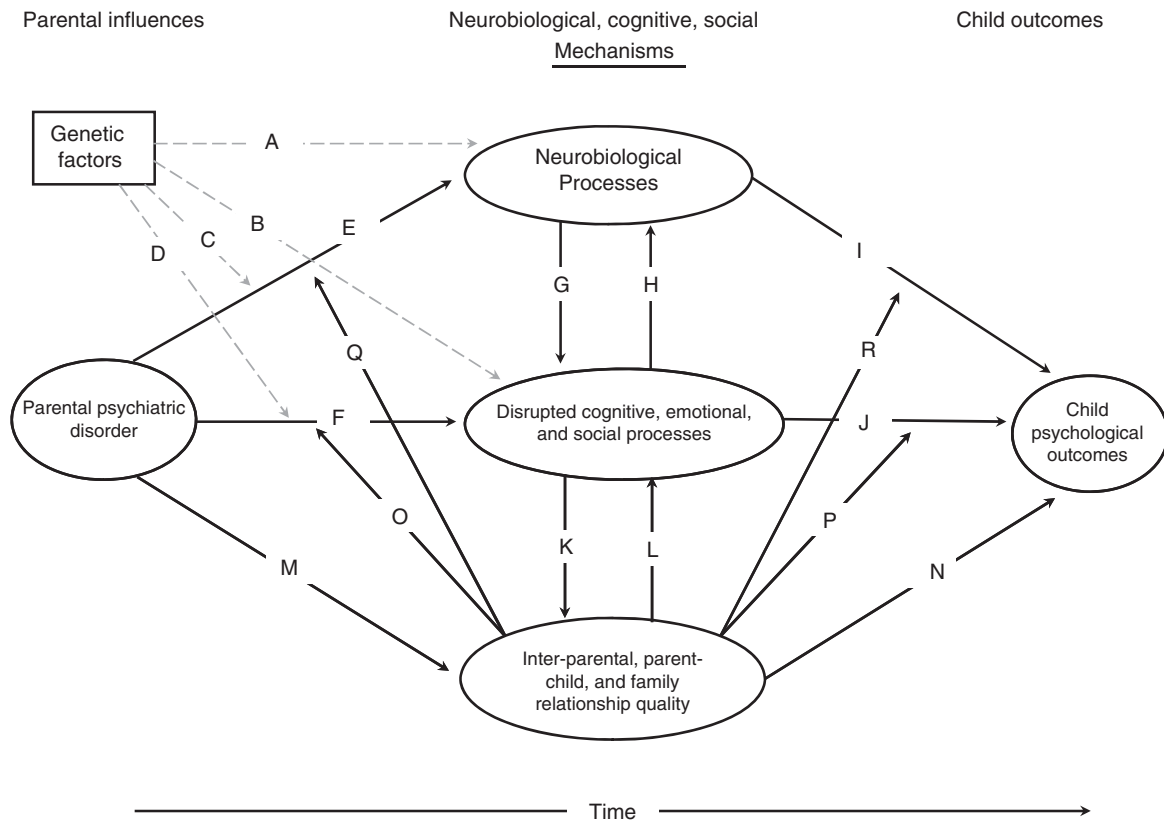

Figure 28.1 Theoretical model of the intergenerational transmission of psychopathology.

disrupt patterns of functional family relationships (e.g., parenting practices), which then leads to elevated psychopathology in children (see Figure 28.1, i.e., Paths E + G + K + N).

Other theoretical possibilities also exist (e.g., Paths E + G + H + I; F + K + L + J), capturing not only unidirectional processes, but bidirectional and transactional patterns. While these respective configurations of intergenerational transmission of psychopathology represent plausible mediating processes, the model also incorporates the propensity for possible moderating influences. For example, genetic factors are recognized as relevant to the transmission of psychopathology from parent to offspring (see Chapters 12 and 24). Children born to mothers who are depressed might inherit DNA that places them at elevated risk for depression (Goodman & Gotlib, 1991). These susceptibility factors may also disrupt neurobiological and cognitive-emotional-social processing (Paths A and B). Specifically relating to the role of genetic transmission in studies that examine the etiology of psychopathology in childhood, recent molecular genetic studies have reported allele (G) \times environment (E; specifically child maltreatment) interactions (genetic moderation) predicting children's antisocial behavior and conduct problems (Caspi *et al.*, 2002; Kim-Cohen *et al.*, 2006; Rutter *et al.*, 2009). Building on this body of evidence, it is increasingly recognized that rather than serve as a

direct cause of disrupted individual psychological functioning, genetic factors may interact with adverse environmental conditions (gene-environment interplay), promoting more negative developmental outcomes (e.g., Paths C and D).

As a further example of a process-orientated approach to understanding the intergenerational transmission of psychopathology, each of the proposed mediators presented in Figure 28.1 may also serve to moderate specific pathways linking parental psychiatric disorder to offspring outcomes. For example, negative family interaction patterns may accentuate the association between parental psychiatric disorder and disruptions in children's neurobiological processing (Path Q), or between levels of cognitive-emotional-social processing and children's symptoms of psychopathology (Path P). The model presented in Figure 28.1 offers a conceptual framework through which understanding of intergenerational transmission processes may be represented schematically, offering testable hypotheses that may be extended and amended relative to the specific index of parental psychiatric disorder that is being examined. We review primary areas of psychiatric disorder and associated outcomes for children in the following sections. First, however, we provide (1) a very brief synopsis of research findings that illuminate the heterogeneous nature of psychopathology as conveyed through intergenerational risk and the mediating and

moderating mechanisms through which this heterogeneity may be explained, and (2) we provide a brief primer for the clinical reader of the specifics of mediating and moderating variables as they are conceptually and statistically examined, with features of mediation and moderation also addressed in other relevant chapters (see Chapters 12 and 24).

Intergenerational transmission of psychopathology: one size does not fit all

Despite evidence that increased risk for psychopathology is conferred to children of parents with psychiatric disorder, emerging evidence suggests that a given psychiatric risk in a parent (e.g., depression) may convey one or more risk outcomes in children (e.g., depression and/or conduct problems); intergenerational transmission of psychopathology is not necessarily phenotype specific (e.g., parent depression to child depression; parent antisocial behavior to child conduct problems). Further, the transmission mechanisms (e.g., parenting behavior) that underlie any such association may vary depending on the particular index of psychopathology considered. As outlined above, past research has suggested that genetic factors passed on from parents to children (G) may explain the pattern of association between specific indices of parent psychopathology and associated outcomes for children, other studies suggest that the environmental conditions (E) experienced by children in the context of parent psychopathology explain transmission effects, with recent studies suggesting that the combination of genetic susceptibility factors and adverse environments ($G \times E$) explain intergenerational transmission associations (see Chapters 12 and 24). Recent studies employing novel research designs that allow disaggregation of genetic and environmental factors underlying associations between parent and child psychopathology find differential results for the relative role of G versus E. For example, Silberg *et al.* (2010), using a Children of Twins (COT) design, noted that associations between parent antisocial behavior and child depression were entirely mediated by environmental factors, with genetic and environmental factors mediating association with child antisocial behavior, and genetic factors mediating association with child ADHD. Specifically relating to the role of parenting as an environmental mediator of associations between parent and child psychopathology, Silberg *et al.* (2010) noted the role of parenting as a mediator in the case of parent antisocial behavior and both child conduct problems and depression. Harold and colleagues echo this pattern of results using a sample of differentially related parents and children conceived through *in vitro* fertilization (IVF) (Harold *et al.*, 2013). Findings from studies using this design, suggest that genetically unconfounded associations between parent and child antisocial behavior are mediated by hostile parenting, while parenting does not mediate the association between parent and child depression (Harold *et al.*, 2011). Findings from these studies illuminate the complexity of genetic and/or

environmental processes that underlie associations between parent and child psychopathology.

The mechanics of mechanism: mediators versus moderators in clinical research

Any question that engages the hypothesized role of a third variable, such that the initial association or link between an independent variable (X, cause) and a dependent variable (Y, criterion) is explained by a mid-level variable may be described as a *mediating variable*. According to MacKinnon (2011), there are two overlapping ways in which mediating variables have been used in prior research, with particular relevance to clinical applications. First, mediation for design where interventions are employed to change a mechanism (mediator) through which a factor exerts influence over an outcome or criterion. Second, mediation for explanation where mediators are selected after an effect of X to Y has been demonstrated to explain the mediating process by which X affects Y. The use of mediating variables for design is central to interventions designed to affect or influence behavior (e.g., hostile parenting practices in the context of parental antisocial behavior). A *moderating variable* is a variable that modifies the form or strength of the relationship between an independent and a dependent variable. Moderated effects are also more commonly known as interaction effects. Unlike a mediating variable, a moderating variable is not part of a causal sequence or chain; rather, the moderator qualifies the relationship between X and Y (e.g., sex, group allocation, genetic predisposition, IQ, temperament).

Moderating and mediating variables may also work together in explaining psychiatric risk effects on psychological outcomes in children. There are two major types of effects that combine moderation and mediation as described in the literature (see Preacher *et al.*, 2007) (1) moderation of a mediated effect, where the mediated effect is different at different levels of a moderator variable (e.g., hostile parenting practices (Med) in the context of parent antisocial behavior (X) and child conduct problems (Y) affects behavioral outcomes for boys but not girls, the role of the mediator is therefore moderated by child gender, (2) mediation of a moderated effect, where the effect of an interaction (moderated effect) on a dependent variable is mediated (e.g., a parenting-focused intervention targeting adult antisocial behavior on child depression may be explained by parent gender, such that the interaction between the intervention and adult antisocial behavior is due to differential time spent with child between mothers versus fathers, the role of the moderator is therefore mediated by parental gender as measured through time spent with child). Despite the conceptual appeal of moderated-mediation and mediated-moderation, particularly from a clinical standpoint, few research studies simultaneously include both mediating and moderating variables, at least in part because of the difficulty of specifying and interpreting these models, relative to clinical applications.

Parental psychiatric disorders

The issue of the effects of parental disorder on children applies both to mothers and fathers, although the majority of research has been conducted with mothers (Ramchandani *et al.*, 2009). Some disorders are especially common in the child-bearing years, such as depression, anxiety, eating disorders, and alcoholism. In the following section, we primarily focus on the psychiatric or psychosocial outcomes for children. Alongside these, other difficulties, such as the impact on family functioning, need to be considered.

Depression

Depression is the most common psychiatric condition among women of childbearing age and has a point prevalence of over 8% (Weissman *et al.*, 1988). Depression affecting parents of older children has revealed consistent associations with difficulties in their children. A recent meta-analysis of the impact of maternal depression on four domains of offspring psychopathology: emotional disorders, behavioral disorders, general psychopathology, and negative/positive affect or behavior found that the risks were increased in all four domains (Goodman *et al.*, 2011). The effect sizes, however, were relatively small. Children from low-income families, children of single mothers, and girls seem to be most affected. More severe and chronic parental depression is associated with a higher risk for offspring disorder (Goodman *et al.*, 2011), more specifically, an increased risk of behavioral problems, such as conduct disorder in school-aged children, and an increased risk of psychiatric disorder in adolescents, particularly depression and anxiety disorders (Tully *et al.*, 2008; Harold *et al.*, 2011). This risk persists into adulthood; a 20-year longitudinal study found that offspring of depressed parents had a threefold increase in depressive and anxiety disorders and substance dependence, as well as an increased risk of physical health problems and greater social impairment (Weissman *et al.*, 2006). Other research has found an increased risk of insecure attachment to the depressed parent (Martins *et al.*, 2000). Compared to controls, young children of mothers with depression score lower on measures of language and general cognitive development, but again effect sizes were relatively small (Stein *et al.*, 2008; Murray *et al.*, 2010). In low- and middle-income countries (LMICs), there is also substantial evidence that child growth is associated with maternal depression, with an increased risk of child stunting and children being underweight (Surkan *et al.*, 2011).

The postnatal period has been a particular focus of research and clinical work in recent years. This is partly because the infant is entirely dependent on carers for his/her health and development at this time, and because of the emphasis on the benefits of early intervention and prevention (Doyle *et al.*, 2009). Estimates of depression occurring specifically in the postnatal period are approximately 13% (O'Hara *et al.*, 1996). A recent review from high-income countries (HICs) indicates that the prevalence of

“major depression” using diagnostic interviews is lower (4.7% in the 3 months postpartum) (Gavin *et al.*, 2005). Recent studies of LMICs have shown rates to be substantially higher than in HICs, although with considerable variability in rates (Parsons *et al.*, 2012). Those at particular risk of developing postnatal depression (PND) include women with a past history of depression and those who lack social support. Other factors include socioeconomic deprivation and social isolation (Boyce, 2003).

An increasing number of longitudinal studies have identified associations between maternal PND and adverse child outcomes (Murray *et al.*, 2010; Stein *et al.*, 2014.). PND can affect a mother's ability to cope with the care of her infant and limits her capacity to engage positively with the infant in social interactions. PND is also associated with poorer functioning in a number of developmental domains, including child behavior, attachment, and social and cognitive development. The children at most risk are those whose parents are socioeconomically disadvantaged or those where the mother's depression persists (Goodman *et al.*, 2011). The few studies which have followed up children into adolescence, suggest that at 18 years they are at an increased risk for depression themselves (Pearson *et al.*, 2013). Experimental evidence indicates that maternal cognitions associated with depression (rumination) and anxiety (worry) make it difficult for the mother to attend to the child's signals, which in turn impact negatively on mother–child interactions (Stein *et al.*, 2012).

Evidence suggests that parenting is an important mediator of the effects of depression on young children (Leve *et al.*, 2009). However, the effects are not inevitable and are moderated by socioeconomic status, social adversity, education (Lovejoy *et al.*, 2000), and the health status of the non-ill parent (Engle *et al.*, 2013). Thus, in more adverse circumstances or where parents have low levels of education, depression is more likely to impact on the quality of parenting and thereby child development (Stein *et al.*, 2008), but wider healthy family relationships may ameliorate (moderate) this relationship.

Antenatal psychiatric disorders are also associated with disturbances in child development (Van den Bergh *et al.*, 2005; Talge *et al.*, 2007). Whether the associations observed arise directly through effects on the fetus, genetic confounds or because depression continues into the postnatal period, are difficult to determine (Batenburg-Eddes *et al.*, 2012). There is now some evidence of association with increased rates of ADHD (Galéra *et al.*, 2011), and depression in late adolescence for those whose mothers had antenatal psychiatric disorders (Pearson *et al.*, 2013). However, the causal underpinnings underlying these associations remain unclear.

There has been some research on the effects of depression in fathers in the postnatal period. One large longitudinal study showed that paternal depression was associated with increased risk of behavioral problems at 3 years, largely in boys. There was also an increased risk of both conduct and emotional problems for both sexes at 8 years (Ramchandani *et al.*, 2009).

Anxiety

Anxiety disorders in parents are also common. Social phobia is the most prevalent of the anxiety disorders and it has a lifetime rate of 13% (Kessler *et al.*, 1994). Children of parents with anxiety disorders have been shown to have a markedly increased rate of anxiety disorder themselves (up to 7 times) (Turner *et al.*, 1987) and an increased rate even compared with offspring of substance-abusing parents (Merikangas *et al.*, 1998; Biederman *et al.*, 2006). Social phobia has been reported in almost a quarter of the children of patients with social phobia (Mancini *et al.*, 1996). Antenatal anxiety has also been associated with a range of offspring problems, including both emotional and behavioral problems (Glover, 2011). Postnatal anxiety also shows negative effects on both psychological and somatic outcomes (Murray *et al.*, 2009; Glasheen *et al.*, 2010).

Two aspects of parenting as modes of transmission of anxiety have been of particular interest. The first is through modeling of anxious behavior, for example, where parents respond to strangers in an anxious/wary way, young children may show avoidant behavior (Murray *et al.*, 2009). The second is via the transfer of information through parental cognitions, for example, in conversations with children, anxious parents express fear, particularly of threat about the future, or the consequences of actions. These in turn impact on the child's behavior and cognitions (Murray *et al.*, 2009). When cognitions of mothers with postnatal anxiety disorders were primed, adverse effects on their responsiveness to their infants were evident, which in turn was associated with infant withdrawal and negative mood (Stein *et al.*, 2012).

Eating disorders

Eating disorders are common among women of child-bearing age (Fairburn *et al.*, 2003), and the prevalence may be rising. The majority of such women suffer from bulimia nervosa or eating disorder not otherwise specified (EDNOS), which are significantly impairing but do not fulfill all the criteria for anorexia or bulimia nervosa. Only a small minority suffer from anorexia nervosa as low weight affects their fertility. Maternal anorexia nervosa (active or past) is associated with low birth weight, increased rates of prematurity, and even an increased risk of miscarriage. This is likely to be mediated by both low maternal BMI pre-pregnancy and smoking (see Micali *et al.*, 2009 for a review).

Children of mothers with eating disorders are particularly vulnerable during infancy and adolescence (Patel *et al.*, 2002). Such children are more likely to grow more slowly and some even fail to thrive (Patel *et al.*, 2002). Two longitudinal studies have shown that children of mothers with eating psychopathology are more likely to experience conflict during mealtimes when 5 years of age. They are also more likely to have concerns about their body shape and weight and to use dietary restraint; this is possibly more common in girls (Stice *et al.*, 1999; Jacobi *et al.*, 2001; Stein *et al.*, 2006a, also see Chapter 71). Data from the Avon Longitudinal Study of Parents and Children (ALSPAC)

study showed that children whose mothers had a history of anorexia nervosa or bulimia nervosa were at increased risk in the preschool period of a range of difficulties such as emotional, conduct, and hyperactivity disorders for girls and emotional problems for boys for children of women with anorexia nervosa (Micali *et al.*, 2014). Girls of mothers with bulimia nervosa were more likely to show hyperactivity and boys had more emotional and conduct disorders.

Alcohol and substance misuse

Alcoholism and substance misuse are conditions that are easily overlooked. They are not uncommon among adults of child-bearing age, and are associated with higher risks among the children (Lieberman, 2000). Heavy alcohol consumption during pregnancy has been recognized as potentially harmful to the fetus (Stratton *et al.*, 1996). In particular, it may result in fetal alcohol syndrome, which is characterized by minor facial anomalies, impaired growth, and developmental delay (Jones *et al.*, 1973).

The worldwide prevalence of this condition varies with estimated rates of 2–7 per thousand children in the United States contrasting with rates of around 50 per thousand in the Western Cape of South Africa (May *et al.*, 2009). It is a condition associated with poverty and disadvantage (Abel, 1995). In addition to this well-described syndrome, it seems plausible that prenatal alcohol exposure could exert neurotoxic effects in the absence of facial or other abnormalities. Such a condition has been termed alcohol-related neurodevelopmental disorder (Stratton *et al.*, 1996). Although this condition is purported to be more common than fetal alcohol syndrome, making a causal link in an individual case is very difficult and more research is warranted (Gray *et al.*, 2009). Alcohol and drug problems can exist alone, but often coexist with depressive disorder. With regard to problems in older children, a large longitudinal study found that adult children of alcoholics had an increased lifetime prevalence of mood, anxiety, and abuse/dependence disorders and possibly also schizophrenia when compared to offspring of nonalcoholic parents (Cuijpers *et al.*, 1999). Rates were especially high for the children of fathers with drinking problems.

Of particular relevance to the early postpartum period is the problem of withdrawal syndrome. Newborn babies of mothers who are drug-dependent are already at higher risk than nonexposed infants for perinatal complications such as prematurity and low birth weight. A withdrawal syndrome can develop in cases where the mother has been using opiates, but this can also occur with other drugs such as benzodiazepines. The symptoms and signs seen in the infant depend on the drug used, and the risk and severity of these symptoms diminish significantly if the mother has been abstinent for more than a few days (Hudak *et al.*, 2012). In circumstances where a child exhibits a withdrawal reaction, the issue of child protection will also require careful consideration and, where parents have a continuing substance addiction, child protection will be a

continuing concern for the professionals involved (Gray *et al.*, 2009).

Schizophrenia and other psychoses

Some severe psychiatric disorders, such as schizophrenia, are associated with reduced fertility. Compared with the general population, parents with schizophrenia have a greatly increased risk of having a child who later develops schizophrenia (Gottesman *et al.*, 1991; Bergman *et al.*, 1995). In addition, although most of the study samples have historically been relatively small, they do suggest that children of affected parents have a raised risk of a range of other psychiatric diagnoses; including ADHD, autism, anxiety disorders, and depressive disorder. More recent, larger scale population studies affirm this pattern of results (see Sullivan *et al.*, 2012). Children of parents with such disorders may have to cope with enormous variations in parental mood and behavior as well as sometimes having to provide substantial care for their parents.

With respect to bipolar disorder there is a high risk of offspring developing affective disorders with a smaller specific risk of bipolar disorder. For example, in a 12-year prospective study of the adolescent children of parents with bipolar disorder, lifetime prevalence was found to be 13% for bipolar spectrum disorders and 45% for mood disorders (Mesman *et al.*, 2013). Other studies report even higher rates for both bipolar disorder (morbidity risk 33.0 vs 2.8) and earlier onset depression (by age 12 years, morbidity risk 34.2 vs 7.5) in children of parents with bipolar disorder (Henin *et al.*, 2005).

Postpartum psychosis is less common, affecting between 1 and 2 women per 1000. Episodes are usually affective in type and the most notable risk factor is a past or family history of affective psychosis. These disorders can have a devastating effect on the family. The impact on an infant can manifest both in terms of a mother's ability to care for herself and her infant (poorer quality caregiving), and by the infant becoming the focus of a mother's delusional beliefs. Fortunately, this latter problem is a relatively rare occurrence; nevertheless, when it does occur, provision of a high level of treatment, supervision, and support becomes necessary. Longer term studies, have generally been very small in size and some suggest a relative absence of ill effects. However, one study which followed-up offspring for an average of 23 years following an episode of severe puerperal disorder, found an increase in adult psychiatric illness amongst offspring whose mothers had a puerperal episode compared to siblings not exposed to a postnatal episode (Abbott *et al.*, 2004). These were mainly anxiety and depression. One of the most important issues concerns further pregnancies. The risks for subsequent psychotic episodes rise markedly with each additional episode and it is important that parents are counseled about future pregnancies and that if they decide to go ahead, appropriate measures are put in place to support the family and to promptly deal with any problems that arise.

Overall patterns of association suggest a degree of specificity in some of the links between the disorders in parents and

offspring, but more recent studies highlight more nonspecific intergenerational associations.

Psychiatric disorders in fathers

Where relevant the effects of paternal disorders have been mentioned. Overall, most psychiatric disorders that affect fathers are associated with an increased risk of behavioral and emotional difficulties in their children, similar in magnitude to that due to maternal psychiatric disorders (see Ramchandani *et al.*, 2009). Findings indicate that boys are at greater risk than girls, and that paternal compared with maternal disorders might be associated with an increased risk of behavioral rather than emotional problems and be independent from maternal psychiatric disorders.

Parental physical disorders

The association between physical illnesses and child disturbance and development has received less attention than parental psychiatric disorder. Nonetheless, some physical illnesses are relatively common in adults of parenting age, and a number of chronic conditions have been shown to affect women of childbearing age; almost 10% of women aged 18–44 report some restriction of activity caused by chronic disease (Misra *et al.*, 2000).

In this relatively limited research field, much of the research has focused on cancers that affect parents. Approximately 21% of newly diagnosed cancer patients are between the ages of 25 and 54; a time when people are likely to have dependent children (Krattenmacher *et al.*, 2012). Breast cancer alone affects 1 in 9 women in the Western world. Over a quarter of those affected have children living with them and consequently this has tended to be the most frequently studied condition. Reviews of the effects of parental cancer on children's development reveal a relatively complex story. A significant minority of children become distressed or develop psychological problems. There is a relatively consistent increase in emotional problems seen in adolescent offspring of parents with cancer (Krattenmacher *et al.*, 2012). However, there is less evidence regarding emotional problems in younger children. This lack of research does not mean that they are unaffected, as qualitative interview studies have highlighted common feelings of guilt and distress, but these may not always translate to changes in measured scores on psychological questionnaires. The effects on children appear to be moderated by a number of similar factors that amplify or ameliorate the effects of parental psychiatric illness on children. A recent systematic review highlighted that the most important factors influencing children's adjustment were family-related factors, with better family functioning, including marital adjustment, being associated with better child adjustment (Krattenmacher *et al.*, 2012). Parental depressive mood was associated with more problems in children's psychosocial functioning as was the severity of disease.

HIV/AIDS has become the largest ever pandemic and in sub-Saharan Africa it has reached catastrophic proportions. Young people of child-bearing age, particularly women, are most affected, with, for example, 10 million people in sub-Saharan Africa aged 15–24 being infected—the next generation of parents. There is now substantial evidence that the offspring of mothers with HIV are at increased risk of poor development, psychological problems, compromised growth, and even survival (Sherr *et al.*, 2013; Clark *et al.*, 2013). Furthermore, these risks also apply to uninfected children of mothers with HIV (Sherr *et al.*, 2013). One of the most important mechanisms is likely to be through compromised maternal care, especially in the context of maternal depression. Maternal depression has been shown to be relatively common among women attending antenatal clinics and being tested for HIV/AIDS (Rochat *et al.*, 2006), which is when most women in Africa receive their diagnosis.

A recent review (Chi *et al.*, 2013) found that AIDS orphans and vulnerable children had poorer psychological well-being compared to children from HIV-free families or children orphaned by other diseases. In terms of mechanisms, Cluver *et al.* (2013) found that neither AIDS orphanhood nor parental AIDS illness were directly associated with psychological distress, educational access, or sexual health. Rather, the influences on the child are derived from indirect effects such as parental disability, poverty, community violence, stigma, and child abuse, which together interact through chain effects (see Chapter 46).

Studies of parents with other illnesses have included diverse groups of physical health problems, such as diabetes and multiple sclerosis (Korneluk *et al.*, 1998). Some studies have compared children of these parents with children from “healthy” families, and some with families where a parent has a psychiatric disorder. Overall, children in families where a parent has a physical illness have higher rates of anxiety and depression than children in “healthy” families. It should be stressed that most of the studies were relatively small, and had limited scope to investigate the mechanisms by which any increased risk may occur. Similar moderating influences, such as those apparent in the literature on parental cancer outlined earlier, are likely to operate (Pederson *et al.*, 2005), although there is a lack of research addressing this at present. Given the high prevalence of chronic physical illnesses in adults of parenting age, further research to understand the way in which increased risk to the child occurs is important, particularly as it may lead to the development of effective interventions. Anxiety and depression are clearly only two areas of child functioning that may be affected by parental ill-health. They are the most studied, but some studies of functional disorders, such as irritable bowel syndrome, have also examined responses to illness in the children themselves (Crane *et al.*, 2004). These studies suggest that a lower parental threshold for seeking help may potentially affect children’s interpretations of symptoms as they grow up to take increasing responsibility for their own health.

Clinical implications

Parental psychiatric disorders

It is important to be aware when seeing parents with psychiatric problems that their children may be at risk, and that a careful assessment needs to be made. A helpful overall framework for assessing the potential risks to children where a parent has a psychiatric disorder is provided by Rutter (1989). Careful assessment should include the areas which are most likely to be affected by the parental disorder. These have been outlined, but include specific difficulties in parental interaction with their children, the quality and type of care the parent is able to provide, the presence of extended family, and the quality of the parental relationship. Review of these factors in the past history, as well as at the present time, can give useful insight into any potential areas of difficulty that may exist. A thorough and individualized assessment of this kind will be the best guide to the areas where intervention (if required) is most likely to be of benefit. Clinicians can also play a practical, positive role in providing support, information, and treatment to parents affected by psychiatric disorder. There is sufficient evidence to suggest that treating parental psychiatric difficulties will, in many cases, contribute to better outcomes for the child and family (Cobham *et al.*, 1998; Weissman *et al.*, 2006).

When children are referred for psychiatric problems, clinicians should again be aware that their parents may have a disorder and that assessing the parent’s mental health and treating any disorders found, may be an important part of the overall treatment package. This is now being recognized in treatment guidelines; for example, the UK NICE (National Institute for Health and Care Excellence) guidelines for the treatment of depression in children and young people specifically identify the assessment of parental mood as part of the clinical assessment. It can be helpful to involve adult mental health services, although this is not always possible. Clearly, assessments need to be conducted cautiously and sensitively as parents can easily feel blamed. When children are referred for problems and the family is being seen, parents can sometimes appear relatively lively at initial appointments, belying underlying difficulties. It is important, with parental consent, to obtain information from people outside the immediate family about the situation at home. For example, parents may be reluctant to acknowledge that they spend long periods of time in bed and are unable to provide necessary support for their children. The establishment of close collaborative links with adult psychiatric services is likely to lead to the most positive outcomes for families where a parent has chronic, severe psychiatric difficulties. However, this is not always possible either because such services are not readily available, or because of differences in thresholds for accepting referrals. The decision about treatment can sometimes be a difficult clinical judgment. When the ideal circumstance of close joint management with adult services is not available, a clinician might be able to liaise with the parent’s general practitioner, but in some circumstances provision of treatment directly to the

parent within the child and adolescent mental health setting may be most appropriate, such as systemic family therapy.

Occasionally, in very serious cases, there is a concern about neglect and maltreatment in which case social services may need to be involved (see Chapter 29). The critical point is to assess, recognize, and arrange appropriate management of parental difficulties, as well as the child's presenting problem. In addition, it is important to monitor treatment progress. Face-to-face follow-up appointments are ideal, but with the widespread use of mobile phones, a great deal can be achieved through telephone calls and text messages (Miklowitz *et al.*, 2012).

Common psychiatric disorders in parents

There is substantial research literature on the treatment of children who are diagnosed with a psychiatric disorder. However, there is less research on interventions to help families where a parent has such a disorder; to either prevent or manage problems in the children if they manifest themselves. Studies that have addressed this question have mainly concerned parental depression, and it has become clear that it is essential to treat the parental disorder to improve child outcome. One large treatment trial of 7- to 17-year-old children whose mothers were treated with antidepressant medication found that maternal remission within three months (occurring in approximately one-third of women) was associated with a significant decrease in child and adolescent disorders and symptoms (Weissman *et al.*, 2006). A recent meta-analysis of preventative interventions for children of mentally ill parents found a range of benefits (Siegenthaler *et al.*, 2012). The risk of developing the same illness as the parent was decreased by 40% and emotional symptoms (depression, anxiety) specifically were decreased. Some trials found benefits for behavioral symptoms but overall this was not significant. The trials comprised interventions directed at the parent, the couple, and the family but there were no differences across these groups. The authors suggest that the positive effects may have been due to more nonspecific factors such as attention and empathy, which are common to most treatment. However, it should be noted that all treatments in their meta-analysis were structured with a clear focus and therefore may not generalize to treatments with less structure and a more general focus. A number of studies have specifically been aimed at preventing depression among adolescents of depressed parents. One trial of a group cognitive intervention for adolescents of depressed parents found that the treatment reduced the risk of depression up to 15 months posttreatment. At the two year follow-up, a significant preventative effect persisted but at a diminished level (Clarke *et al.*, 2001). A recent large trial, using a group cognitive behavior prevention program targeting a similar group, added six-monthly continuation sessions with the aim of prolonging the effects. This trial showed significant sustained benefits in terms of preventing onset of depressive disorders at the 3-year follow-up (Beardslee *et al.*, 2013). A cautionary note should be applied in interpreting this body of evidence, in that recommendations highlighting the benefits of treating parent

symptoms in relation to offsetting expression of symptoms in the child (offspring) do not preclude recommendations to continue to treat/focus on child symptoms.

With respect to parental depression occurring in the early years, treating the depression alone does not generally improve parent-child interaction and specific efforts need to be targeted at improving mother-child interaction in order to improve child outcome (Forman *et al.*, 2007). There is now emerging evidence for the benefit of therapies such as video-feedback, which aim to focus parents' attention on infant cues and communication, leading to improvements in both child attachment security and child competence (Van Doesum *et al.*, 2008). A similar study using video-feedback, in the context of maternal postnatal eating disorders, compared to control treatment, showed benefits in terms of reduced rates of mother-child conflict, enhanced maternal facilitation of infant behavior, and increased infant autonomy. Both groups maintained good infant weight with no differences between them (Stein *et al.*, 2006b).

Emerging evidence suggests that disturbed parental cognitions may be a feature of the transmission mechanism from parental depression to child outcomes. These cognitive disturbances comprise a narrowed state of attention, where the parent is overwhelmed by recurrent intrusive thoughts known as rumination in depression and worry in anxiety (Watkins, 2008). This narrowed focus of attention can have adverse effects on an individual's capacity to attend and respond to the outside world. This may affect appropriate responsiveness and attention to a child. It is critical to help a parent to attend to a child's communication, especially facial cues, speech, and mood, and to respond appropriately in order to move the parent's focus of attention from internal thoughts to those of communication patterns with children (Juffer *et al.*, 2008; Stein *et al.*, 2009, 2012).

In LMICs where trained healthcare professionals may not be available, local community health workers can play an invaluable role in supporting families and can be trained to provide interventions for parents and young children (Rahman *et al.*, 2008; Cooper *et al.*, 2009). In particular, a small number of randomized trials in LMICs have demonstrated that psychological interventions delivered by local health workers may be helpful in reducing maternal depression and may have a positive impact on some aspects of child development. In Pakistan, a perinatal intervention program using cognitive behavioral principles delivered by primary care health workers, compared with enhanced usual care, reduced rates of maternal depression, although infant growth was not affected (the principal outcome) (Rahman *et al.*, 2008). Parents reported that they played more with their children, although the quality of parent-child interaction was not measured. A second study was conducted in a socioeconomically disadvantaged South African community, although not specifically in the context of depression (Cooper *et al.*, 2009). The home-based intervention focused specifically on helping mothers to attend to the details of the infant's communication and to respond sensitively. It led to improvements in the quality of mother-child interaction and increased rates

of secure attachment. There is some evidence that community “participatory learning and action” groups (focused on education and maternal and newborn health practices) which are principally aimed at reducing neonatal mortality rates, may also reduce maternal depression (Tripathy *et al.*, 2010).

Psychotic disorder

Children of parents with psychotic disorders often experience substantial unpredictability and lack of consistency in the household as well as occasional absences due to hospital admissions. Parents often display major fluctuations in mood and behavior. Children need support not only to cope with these but also to realize that such behavior is part of their parent’s illness. They need time and care from “healthy adults” as well as opportunities to have positive experiences with their ill parent. Children often want to know whether they are also likely to develop the disorder and thus supportive and open discussions at age appropriate times are necessary. Mothers with puerperal psychosis will often require in-patient care, ideally in a specialist mother and baby unit, where the baby can remain with her mother in all but the most extreme of presentations, and where experienced, skilled staff can provide the level of care and supervision necessary. It is in these circumstances that clinicians have to be particularly aware of the potential danger to the child’s well-being, either through direct risk from a mother with delusional beliefs and/or hallucinations, or through neglect of the child. The need to balance the risk (to mother and child) with the desire to keep families together to promote the development of a positive relationship and facilitate the mother’s recovery requires experienced clinical judgment.

Substance misuse

There have been a number of studies which have investigated the effectiveness of comprehensive programs for mothers with substance misuse in relation to child outcomes (Niccols *et al.*, 2012). Such programs deal not only with substance misuse but also with maternal and child well-being through prenatal services, parenting programs and child-care, or other child-centered services (Niccols *et al.*, 2012). They found that such interventions had positive impacts on birth outcomes and on children’s behavior, growth, and development. This emphasizes the importance of dealing with the associated family environment and parenting factors when attempting to mitigate effects on children. This is especially important given the evidence that there is higher risk for child maltreatment and poorer outcomes for such children (Dunn *et al.*, 2002; Niccols *et al.*, 2012).

Parental physical disorders

There has been little research examining how to mitigate the potential impact of a serious parental physical disorder on children’s development. However, a number of studies have focused on the nature of the communication between parents and children in the context of maternal breast cancer and provide guidance to intervention (Forrest *et al.*, 2006). Individual
